ABSTRACT

Background and study aims Determining the etiology and location of gastrointestinal motility disorders can be challenging. A range of investigations targeting specific areas of gastrointestinal transit are available, but many provide clinical data for a given gastrointestinal region alone or for non-specific whole gut transit, and are otherwise of limited use. Video capsule endoscopy allows endoscopic visualisation of the entire gastrointestinal tract, and may also provide more specific data for regional transit time abnormalities.

Patients and methods Data from video capsules ingested by 71 ambulatory healthy subjects were recorded and analyzed to determine gastric and small bowel transit times in the fasting state.

Results Median, and interquartile range (IQR), gastric transit time was 22 (10–48) minutes, and median (IQR) small bowel transit time was 198.5 (157–240.5) minutes.

Conclusion These data, for the first time to our knowledge, provide references for gastrointestinal transit times among healthy ambulatory subjects using video capsule endoscopy. This potentially strengthens clinical use of video capsule endoscopy in the investigation of patients with suspected gastrointestinal motility disorders.

Introduction

Diagnosis of gastrointestinal motility disorders is challenging partially due to a lack of attainable and useful data from less accessible regions of the gut such as the small intestine [1]. Image-based assessment of intestinal pathology such as x-ray, computed tomography (CT), magnetic resonance imaging (MRI) and direct endoscopic visualisation are frequently relied on to formulate a diagnosis. Current investigations for intestinal motility abnormalities include antro-duodenal manometry, use of radiopaque markers, scintigraphy, hydrogen breath testing as well as newer techniques such as video capsule endoscopy, wireless motility capsule, and MRI-based motility assessment [1, 2]. Scintigraphy is the current gold standard for measurement of gastric emptying and small bowel transit time [2]. However, motility related symptoms are non-specific and often correlate poorly with results of transit time analyses [3].

Many of these methods are time-consuming, expensive, invasive, and some, such as scintigraphy, may involve significant levels of radiation exposure depending on the radioactive meal and clinical indication [2, 4]. Furthermore, there are investigational differences as to which anatomical area of the gut data are obtained from. For example, antro-duodenal manometry record data for specific segments of the intestine, while radiopaque markers and hydrogen breath testing measure whole gut or oro-cecal transit. The wireless motility capsule, by comparison, estimates and records intestinal transit times, following a meal, by measuring changes in pH, temperature and pressure [5, 6]. In addition, both individual variability (of up to 50% [2]) and lack of agreement between investigations on transit times prevents definition of a universal reference range [7].

Few investigations allow both direct imaging of intestinal structures as well as calculation of transit time. Video capsule
endoscopy is one such modality that incorporates luminal visualisation, similar to standard endoscopy, as well as providing transit time data for the stomach and small intestine [7, 8]. Transit time can be calculated through the identification of anatomical landmarks [7]. Video capsule endoscopy may, therefore, have a role in evaluating symptoms suggestive of gastrointestinal motility disorders as well as other intestinal pathology. However, as video capsule endoscopy requires ingestion of a capsule, a suspected stricture contraindicates its use, at least initially [2]. Video capsule endoscopy is also performed in the fasting state as opposed to the fed state required for studies such as the motility capsule. A further current limitation of video capsule endoscopy as a means of investigating motility disorders is the lack of normal values and clinical significance of transit times which hitherto has been unclear. To date, many of the trials of video capsule endoscopy have involved patients with varying medical conditions such as unexplained iron deficiency anaemia [7], occult gastrointestinal blood loss [9, 10], celiac disease [11], functional bowel disorders [12], and critically ill patients [13]. This study aimed to assess gastric and small bowel transit times for healthy ambulatory male and female subjects to establish norms that can inform future diagnostic value of video capsule endoscopy.

Patients and methods
Healthy male and female subjects without pre-existing gastrointestinal symptoms or conditions were included. Exclusion criteria included smokers and pregnant subjects, as well as those with a history of bleeding disorders, inflammatory bowel disease (IBD), irritable bowel syndrome (IBS), previous intestinal surgery, diabetes, and use of medications that affect gastrointestinal motility.

The trial was conducted in accordance with the ethical principles set forth in the current version of the Declaration of Helsinki, the International Conference on Harmonization E6 Good Clinical Practice (ICH-GCP). Ethical approval was granted by The Clinical Research Ethics Committee of the Cork Teaching Hospitals (Cork, Ireland), and informed consent was sought from each subject. The trial was conducted from July to December 2017. The trial was registered at ClinicalTrials.gov under the ID number NCT03228589. This study was performed as a screening of healthy subjects for involvement in this clinical trial.

Capsule endoscopy was performed using the SB3 Pillcam video recording capsule (Medtronic, Ireland). Subjects were fasted from midnight the night before. In the morning, the capsule was swallowed with water and subjects then continued fasting for a further 4 hours. While allowed to leave and carry out usual activities of daily living, the subjects did not engage in strenuous exercise during the 8-hour recording period. The Pillcam receiver belt was returned after this time and video images were retrieved for analysis.

Gastric transit time (GTT) is defined as time from first gastric image to first duodenal image, and small bowel transit time (SBTT) is defined as time from first duodenal image to first cecal image (Fig. 1). All video capsule endoscopies were reviewed by two expert gastroenterologists with experience in interpretation and in cases of discrepancy, a third clinician reviewed the data.

Data were analyzed using Microsoft Office Excel and IBM SPSS Version 24.0 (IBM Corp 2016). Data are reported as mean ± standard deviation (SD) for evenly distributed data, and median ± inter-quartile range (IQR) for non-evenly distributed data.

Results
A total of 71 video capsule endoscopy studies performed, in which first gastric, duodenal and caecal images were identified, were suitable for analysis. The age range was 19–40 years. The mean age, and SD, was 30.49 ± 6.7 years. 40 (56.3%) of the study participants were female, and mean body mass index (BMI), and SD, was 24.25 ± 2.16. All video capsule images were

within normal limits. This was expected as these video capsule studies were performed as screening of healthy subjects for involvement in clinical trial NCT03228589.

Median (and IQR) gastric transit time was 22 minutes (range 10–48), and median (IQR) small bowel transit time was 198.5 minutes (range 157–240.5). A wide range was observed for both gastric (1–179.5 minutes) and small bowel (41.5–422 minutes) transit times. For the female participants, the median gastric and small bowel transit times, respectively, were 27.5 minutes (IQR 12.4–46.3) and 189.2 minutes (IQR 144.25–232.25) minutes. For males, median gastric and small bowel transit times, respectively, were 20 minutes (IQR 8.5–50) and 210 minutes (IQR 165.5–246). The Differences between genders were not found to be statistically significant for either gastric or small bowel transit, $P = 0.754$ (gastric) and $P = 0.195$ (small bowel).

Discussion

Using video capsule endoscopy, in healthy ambulatory subjects a median gastric transit time of 22 (IQR 10–48) minutes was observed in the fasting state. There was no significant difference observed for gender or BMI, which correlates with previous studies using other investigative techniques [14] and studies involving video capsule endoscopy [15]. By means of comparison, Table 1 summarizes gastric transit times outlined in other video capsule endoscopy studies [5, 7,9–12,16–18]. Importantly, only one study was completed using healthy controls [12]. However, these patients remained lying down for 8 hours after capsule ingestion and as opposed to undertaking usual activities of daily living which would be standard protocol for capsule endoscopy. The remainder of the studies were completed on patients for investigation of medical conditions including IBD and gastrointestinal bleeding [9] and iron deficiency anaemia [7] and therefore may not be representative of a “healthy population” for defining a normal reference range. The broad range observed in our data for gastric transit time may be, in part, due to different mechanisms of non-digestible solid emptying, such as phase III migrating motor complex (MMC) and isolated antral contractions [19].

Our video capsule endoscopy data report median small bowel transit time (IQR) of 198.5 (157–240.5) minutes. Again, no significant differences were observed for gender or BMI. Table 1 summarizes data on small bowel transit times from previous studies for comparison. As with gastric transit studies, much of the available data for small intestinal transit time using...
video capsule endoscopy is derived from studies of patients who underwent video capsule endoscopy for another clinical indication. These include investigation of iron deficiency anaemia, occult blood loss [7], celiac disease [11] and comparison of bowel preparations [16, 20]. Similar to gastric transit time, the same single study evaluated small bowel transit times in healthy controls who were lying on a hospital bed for a period of 8 hours [12].

Gastric transit time from our data is similar to that of previous studies, while a possible shorter small bowel transit times is observed. This may be due to subjects in our study being ambulatory for the duration of the recording, or having no co-morbid medical conditions or clinical indications for capsule endoscopy. All video capsule endoscopies were performed in the fasting state, as is standard protocol for video capsule endoscopy, and possibly explains shorter gastric transit compared with fed-state studies such as wireless motility capsule or scintigraphy.

Using our data, video capsule endoscopy may represent an alternative method of measuring gastrointestinal transit in the fasting state, as compared with fed-state techniques such as scintigraphy and breath testing, and also offers dual benefit of direct luminal visualization. Scintigraphy remains, however, the reference gold standard for fed-state measurement of gastric emptying and small bowel transit time [2]. A radio-labelled meal is consumed [21] with imaging taken at incremental stages to estimate transit times against a background reference range [22, 23]. Delayed gastric emptying, for example, may be defined as retention > 90% at 1 hour, > 60% at 2 hours, and > 10% at 4 hours [24]. Radiation exposure is a significant limitation of the technique [4].

13C-gastric emptying breath testing may be used as an alternative to scintigraphy [2, 14]. 13C-labelled substrate disintegrates in the duodenum to release 13-C02 which can be analyzed and quantified by mass spectrometry [25]. The delay between ingestion of substrate and appearance of CO2 is indicative of gastric emptying time [25]. Unlike scintigraphy, this test is unable to assess regional transit abnormalities, instead giving a global overview of gastric emptying and it is also limited by subject baseline metabolic function and absorption [4]. Other investigations, such as wireless motility capsule, also limit radiation exposure and provide intestinal segment transit data but are performed in the fed-state and do not transmit endoscopic images.

Video capsule endoscopy as a technique that is free from radiation, which does not rely on metabolic parameters, that provides endoscopic images for analysis, and is performed in the fasting state, provides a unique dataset in the investigation of gastrointestinal disease.

Conclusion

This is, to our knowledge, the first report of gastric and small bowel transit times using video capsule endoscopy in healthy ambulatory subjects and may provide future reference for gastrointestinal motility disorder investigation. In future, video capsule endoscopy recordings using our data may assist in identifying patients with possible motility disorders who otherwise have normal mucosal findings. Such patients may then benefit from formal fed-state studies such as scintigraphy. Head-to-head study of the gold standard techniques such as Scintigraphy and video capsule endoscopy would be useful to further validate this data.
