ABSTRACT
Intrahepatic cholestasis of pregnancy (ICP) is the most common liver disease specific to pregnancy. The cardinal symptom of pruritus and a concomitant elevated level of bile acids in the serum and/or alanine aminotransferase (ALT) are suggestive for the diagnosis. Overall, the maternal prognosis is good. The fetal outcome depends on the bile acid level. ICP is associated with increased risks for adverse perinatal outcomes, including preterm delivery, meconium-stained amniotic fluid, and stillbirth. Acute fetal asphyxia and not chronic uteroplacental dysfunction leads to stillbirth. Therefore, predictive fetal monitoring is not possible. While medication with ursodeoxycholic acid (UDCA) improves pruritus, it has not been shown to affect fetal outcome. The indication for induction of...
labour depends on bile acid levels and gestational age. There is a high risk of recurrence in subsequent pregnancies.

ZUSAMMENFASSUNG

Background
Intrahepatic cholestasis of pregnancy (ICP) is the most common liver disease in pregnancy. Its prevalence in Western Europe is 0.3% to 0.7%. ICP is an interdisciplinary challenge as it is associated with serious perinatal complications such as prematurity; meconium stained amniotic fluid; neonatal adaptation syndrome; and even intrauterine fetal death. There are no uniform international recommendations. On the contrary, algorithms for pregnancy management vary considerably between international guidelines. There are no national recommendations.

This paper aims to summarise the current literature on intrahepatic cholestasis of pregnancy into structured background information and to provide interdisciplinary consensus-based recommendations based on the available evidence.

Method
In preparation for the present recommendations, a systematic literature search in PubMed and Web of Science was undertaken in October 2020. The database search was performed without time limitation using the search terms “intrahepatic cholestasis of pregnancy”, “obstetric cholestasis”, “intrahepatic cholestasis in pregnancy” and “pregnancy cholestasis” as “OR” links and after exclusion of duplicates yielded 1379 publications. Based on the literature, the statements in the existing guidelines of various multidisciplinary medical societies were reviewed according to the latest evidence-based research. The structure was revised and primarily follows a pragmatic sequence for clinical application while considering didactic aspects. To this end, the criteria of currentness and relevance for clinical management of ICP identified 219 articles from the the search output above. After completion of the full text review, 126 publications were considered for the compilation of the present recommendation. Significant sources from the associated disciplines of hepatology/gastroenterology and neonatology as well as pharmacological product characteristics complemented this review. The guideline #53 “Intrahepatic Cholestasis of Pregnancy” published by the Society for Maternal-Fetal Medicine (SMFM) in November 2020 and the study protocol of the TURRIFIC study (published on 12 January 2021) were included later on. Thus, this paper includes a total of 161 sources (Fig. 1).

Definition
Intrahepatic cholestasis of pregnancy is characterised by a pathological elevation of hepatobiliary retention parameters in maternal blood in pregnancy. Clinical signs are pruritus without skin rash in combination with elevated bile acid and/or transaminase levels in the blood. Complications in ICP are mainly associated with elevated bile acid levels, which is why the bile acid level should be assayed. In case of bile acid levels > 10 µmol/L (fasting) or > 14 µmol/L (postprandial), ICP is likely. Usually spontaneous remission after birth can be expected. ICP is a diagnosis of exclusion.
Hagenbeck C et al. Management of Intrahepatic Tors appears to favour its onset \[10\] due to ethnicity, hormonal and environmental factors. The diagnosis of ICP may also be raised if bile acid levels are unremarkable and the patient has both pruritus and elevated transaminase levels.

**Epidemiology**

ICP is the most common pregnancy-related disease of the liver [1]. Due to ethnicity, its prevalence varies greatly between geographical regions and is significantly higher in Latin American than Caucasian women [2]. The prevalence of ICP is estimated at 0.1% to 15% of all pregnancies worldwide [3,4], even reaching 22% in certain populations in Chile (Araucanian Indians) [5]. The robustness of this data, most of which is over 50 years old, is questionable on the grounds of inconsistent definitions. A recent multiethnic study from Australia found an overall prevalence of 0.7%. High prevalence is seen in pregnant Asian (especially from India and Pakistan) and indigenous women [6,7]. In Sweden, a population-based analysis of 1213668 singleton pregnancies in the Swedish Birth Registry from 1997 to 2009 reported an incidence of 0.32% to 0.58% [8]. Similar data is described for Finland (0.4%) [9]. There is no accurate data on the incidence in Germany.

**Aetiology and Pathogenesis**

ICP is multifactorial and not fully understood. A combination of genetic disposition, hormonal and environmental factors appears to favour its onset [10–13]. It is caused by impaired hepatobiliary transport resulting in retention of substances physiologically excreted with bile. Membrane-bound transport systems of hepatocytes are responsible for the elimination of bile acids and other toxic substances. The processes take place via ATP-binding cassette transporters (ABC), whose expression is regulated via transcription factors, such as FXR and SXR/PXR [14–16]. These transport processes may be affected by various mechanisms [17–20]:

1. Genetic mutations alter the expression or function of membrane-bound transporters such as ABCB4, ABCB11 and ATP8B1.
2. Endogenous and exogenous substances, such as steroid hormones and medication (cetirizine, methyldopa, macrolide antibiotics, etc.), can interfere with transcription factors regulating the activity of the hepatobiliary transport system [14–16,21–24].

3. One result of the reduced excretion is the accumulation of toxic substances, which has a negative impact on the function and expression of transport proteins [25].

The retention of hepatobiliary substances such as bile acids and progesterone sulphates leads to elevated blood levels with accumulation in organs resulting in cytotoxic and hormone-mediated organ dysfunction.

The primary bile acids are conjugated with glycine and taurine and secreted into the duodenum. Glycine-conjugates predominate in unremarkable pregnancies, whereas in ICP the blood levels of toxic taurine-conjugates are elevated [26]. In the in vitro animal model, taurine-conjugates have an irreversible negative effect on the rhythm and contraction amplitude of neonatal cardiomyocytes [27].

**Risk Factors**

- Table 1 lists the risk factors for ICP development. Genetic mutation variants (see above) and previous or concomitant hepatobiliary disease [28–30] in particular, as well as elevated maternal oestrogen levels, favour the development of ICP [22].

High oestrogen levels in multiple pregnancies [31] as well as in early pregnancy after ovarian hyperstimulation [32,33] are independent risk factors. The prevalence in large population twin pregnancies has been reported at 6.2–8.7% [6,34,35], in analyses of small case numbers up to 22% [31]. Changes in progesterone metabolism leading to large amounts of sulphated progesterone metabolites may also contribute to saturation of hepatocellular...
transport systems and cholestasis-inducing reduction of bile secretion [21].

There is evidence that vaginal and oral progesterone application as part of treatment or prophylaxis of preterm birth increases the risk of ICP [3,36]. Other studies were unable to confirm this correlation [37].

The geographic and seasonal variability of ICP with an increase in winter months suggests that environmental factors may modulate the expression of the disease [7,38]. Specific causal factors in the environment have not been identified. Low dietary selenium and vitamin D levels (reduced sunlight exposure) are part of the debate [39,40].

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
Hepatobiliary diseases are predisposing, in particular hepatitis C. There is no possibility of preventing ICP in case of existing risks factors.

Maternal risks
Maternal prognosis during pregnancy is favourable. The mainly nocturnal pruritus can be quite distressing, even agonising. The resulting mental stress can be exacerbated by insomnia and fatigue. However, the severity of the pruritus does not correlate with the maternal bile acid serum level [48,49].

In addition, the course of pregnancy can be affected by comorbidities such as diabetes mellitus/gestational diabetes and arterial hypertension/pre-eclampsia [8]. Compared to pregnancies without ICP, the incidence of gestational diabetes is higher (13.6% vs. 8.5%, OR 1.68; 95% CI 1.04–2.72, p < 0.03), as is the incidence of pre-eclampsia (7.78% vs. 2.41%, OR 3.74; 95% CI 12.0–99 µmol/L; p < 0.0001) [50–52]. The probability of pre-eclampsia increases the earlier ICP manifests in pregnancy. The time lag is about 2–4 weeks, with proteinuria usually preceding hypertension [53]. The coincident presence of acute fatty liver in pregnancy has been described, but without proven causality [54]. Prolonged prothrombin time may be secondary to ICP-induced steatorrhea and the use of bile acid complexing agents (e.g., colestyramine) [55] with subsequent vitamin K deficiency, thus increasing the peripartum bleeding risk [56–58]. In an ICP cohort of 348 pregnant women treated solely with UDCA, postpartum blood loss did not differ from the normal population [59].

An increased rate of cardiac arrhythmias has been described, the cause of which is a direct arrhythmogenic effect of bile acids on adult cardiomyocytes [60–63]. This observation has no clinical consequence.

In the long term, patients who have experienced ICP are at increased risk of developing various liver, biliary, pancreatic; and metabolic diseases (see section on “Postpartum care and follow-up”) [10,30,64,65].

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
The severity of the pruritus does not correlate with the bile acid level. ICP has been shown to coincide with the development of gestational diabetes and pre-eclampsia.

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
The maternal prognosis of ICP for the pregnancy is favourable. Severe maternal complications are not expected.

Fetal and neonatal risks in ICP
Bile acids accumulate in the placenta, fetus and amniotic fluid [3,66]. They can thus harmfully affect the fetus.

Stillbirth – intranatal fetal demise (IUFD)
Stillbirth is the most feared complication of ICP. For singleton pregnancies, the prevalence is 0.83% compared to 0.32–0.44% in healthy pregnant women [67,68]. Currently, there are no predictive markers linked to the event of IUFD. The aetiology is poorly understood. It is argued that fetal peak bile acid levels are crucial and that toxic levels of taurine-conjugates induce fetal arrhythmias and vasocostriction of the chorionic veins [69–71]. Even if placental morphology is altered [72,73], intrauterine death is an acute event.

The level of the bile acid concentration affects the risk for the onset of stillbirth. Common clusters for risk determination are levels up to 40 µmol/L, 40–99 µmol/L and ≥ 100 µmol/L [74–78]. In a recent meta-analysis of individual patient data by Ovadia et al. of 4936 women with ICP, the IUFD rate increased significantly after gestational week 34 when a bile acid level ≥ 100 µmol/L was exceeded. The prevalence in singleton pregnancies was 3 in 2310 women with serum bile acid levels < 40 µmol/L (0.13%; 95% CI 0.13%–0.44%), 4 in 1412 women (0.28%; 0.08–0.72) with levels of 40–99 µmol/L (HR 2.35; 95% CI 0.52–10.50; p = 0.26) and 18 (3.44%; 2.05–5.37) in 524 women with levels ≥ 100 µmol/L (HR 30.50; 8.83–105.30; p < 0.0001) [68].

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
There is an association between bile acid level, gestational age and occurrence of stillbirth.
Preterm birth

Increased rates of indicated and spontaneous preterm birth have been described in women with ICP [3, 8, 56, 57, 74, 79–84]. In studies the iatrogenic preterm birth resulting from a physician’s decision to deliver is consistently and significantly increased [56, 57, 68, 76, 81–83]. Of equal clinical importance is spontaneous preterm birth: the meta-analysis by Ovadia et al. showed an increased risk of almost 3.5-fold (OR 3.47 [95% CI 3.06–3.95]). According to two recent studies, the risk of > 40 µmol/L, Glantz et al. observed meconium stained amniotic fluid in 44% of cases [74]. According to two recent studies, the risk of > 40 µmol/L, Lee et al. found an increased rate of late preterm births among women with ICP (32 + 0 to 37 + 0; aOR 3.30, 95% CI 3.00–3.63), but fewer preterm births before gestational week 32 + 0 (aOR 0.47, 95% CI 0.27–0.81) [8].

Meconium stained amniotic fluid

Meconium stained amniotic fluid at birth is about 4 to 7 times more common in ICP than in women without ICP [83, 85] and depends on the bile acid level. Lee et al. found that in women with bile acid levels > 20 µmol/L each 10 µmol/L increase resulted in a 19.7% increase in meconium stained amniotic fluid [86]. In levels of > 40 µmol/L, Glantz et al. observed meconium stained amniotic fluid in 44% of cases [74]. According to two recent studies, the risk increases by a factor of 1.6–3.5 for bile acid levels between 40 and 100 µmol/L, and by a factor of 3.7–4.6 for levels above 100 µmol/L [76, 85]. A rare but serious complication in meconium stained amniotic fluid is fetal meconium aspiration [87]. The incidence of meconium aspiration syndrome in meconium stained amniotic fluid reportedly is up to 5% [87]. It is characterised by early postnatal onset of severe respiratory distress syndrome with subsequent hypoxia. However, the onset of symptoms can also be delayed. Up to one third of neonates with meconium aspiration require intubation with mechanical ventilation to ensure oxygenation [88]. Routine intrapartum aspiration of meconium stained amniotic fluid is not recommended [89].

Neonatal complications

The risk of the neonate being admitted to a neonatal unit more than doubles with severe maternal cholestasis (12% vs. 5.6%) [34, 68]. The most important factor here is prematurity [90]. Regardless, neonatal respiratory distress syndrome was a specific risk of ICP (aOIR 2.56; 95% CI 1.26–5.18) [91]. Elevated bile acid levels are thought to affect alveolar enzyme function, resulting in surfactant inactivation and a pulmonary inflammatory response with resultant respiratory distress syndrome [92–94]. The association of ICP with other neonatal complications has only been described in small populations. In a retrospective cohort study in infants of mothers with bile acid levels > 100 µmol/L, the retrospective cohort study by Herrera et al. showed a risk, increased by a factor of 5.6 after adjustment for gestational age at delivery, of neonatal morbidity defined as hypoxic ischaemic encephalopathy (HIE), severe intraventricular haemorrhage (IVH, grade 3–4), bronchopulmonary dysplasia (BPD), necrotising enterocolitis (NEC), and postnatal death. However, the total number of events (30 in 785 pregnancies) in this study was small, and no patient developed isolated IVH or HIE [85]. In contrast, Kawakita et al. in a retrospective multicentre cohort study of 233 women after adjustment (age; ethnicity; hypertension; diabetes; BMI; duration of pregnancy; bile acid level; intrahepatic cholestasis of pregnancy; use of UDCA; transaminase level; and pre-existing liver disease) could not demonstrate significant neonatal morbidity [76].

Symptoms and Time of Manifestation

Pruritus is the hallmark symptom of ICP, and in many cases the only symptom reported. Initially, this typically affects the palms and soles of the feet. Sometimes the symptoms undergo secondary generalisation. The subjective spectrum of intensity is described as ranging from “mild” to “unbearable”, markedly intensified at night [95]. In up to 80% of cases, ICP manifests after the 30th week of gestation; the time of manifestation is usually in the late 2nd and early 3rd trimester [47, 82]. Transitory symptoms in the first trimester are associated with ovarian hyper-
stimulation syndrome following in vitro fertilisation [32], while persistent and worsening symptoms are characteristic of naturally conceived pregnancies [96]. While localised and generalised pruritus is a common symptom in pregnancy, in up to 9% of cases it is ICP [47, 97, 98]. However, in more than 80% of cases, ICP manifests as pruritus [34, 56]. Although bile acid deposits in the skin are blamed for pruritus, its severity does not correlate with serum bile acid level [48, 49]. There are no characteristic skin changes. Scratching may cause secondary efflorescence (dermatographica artefacta), which must be differentiated from other pregnancy dermatoses. These include atopic eruption of pregnancy (AEP), polymorphic eruption of pregnancy (PEP; previously known as PUPP: pruritic urticarial papules and plaques of pregnancy) and gestational pemphigoid (syn.: pemphigus gravidarum, gestational herpes) [99, 100]. Accompanying symptoms may include pain in the upper abdomen, nausea, loss of appetite, sleep deprivation, and steatorrhoea. Icterus as an accompanying symptom is quite rare and then occurs with a time lag of about 1 to 4 weeks after the initial pruritus. Some regional data put the incidence of jaundice as high as 25% [74, 100–103]. Symptoms of icterus, such as dark urine and light to greyish stools, should be assessed by differential diagnosis.

**STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**

Pruritus, especially at night and starting on the palms of the hands and soles of the feet, is considered the cardinal symptom of ICP. Accompanying symptoms may include pain in the upper abdomen, nausea, loss of appetite, sleep deprivation, and steatorrhoea.

**Diagnosis**

ICP is a diagnosis by exclusion. The cardinal symptom pruritus is suggestive and should prompt further workup [104]. The medical history must include a family history and physical examination. In unclear cases, especially in the case of primary skin eruptions, dermatological consultation should be obtained. Clinical chemistry panels can further confirm the suspected diagnosis [57]. It is recommended that the patient be seen by an internist to undergo liver ultrasonography to rule out other cholestatic disease. ▶**Table 2** gives an overview of the diseases to be included in the differential diagnosis.

**Laboratory evaluation**

**Bile acids**

Bile acids are synthesised from cholesterol in the liver. First, the primary bile acids (chenodeoxycholic acid and cholic acid) are conjugated with glycine or taurine and secreted into the duodenum. In the intestine, the primary bile acids are transformed into secondary or tertiary bile acids mainly through the action of bacterial enzymes. These are absorbed in the terminal ileum and are thus subject to the enterohpatic circulation. The bile acids detected in the blood originate from intestinal reabsorption. Various assay techniques are used in bile acid measurement. Total serum bile acids (TBA) and bile acid fractions can be assayed by mass spectrometry and liquid chromatography, which is typically performed in specialised laboratories. Total serum bile acids can also be quantified by an enzymatic assay. This assay is also performed in some hospital laboratories. The enzymatic assay does not detect bile acid fractions individually. Accordingly, medication with the tertiary bile acid ursodeoxycholic acid can result in levels that are falsely high.

The reference values of the different assay techniques are based on fasting samples (according to most manufacturers fasting > 12 h). However, postprandial assaying is possible. Numerous studies show that the postprandial elevation in bile acid levels is only minor [105, 106]. If postprandial levels ≥100 µmol/L are reached in some cases (without UDCA administration – depending on the type of assay [see above]), follow-up testing can also measure the fasting level for differential diagnostic consideration.

Fasting healthy pregnant women have a normal bile acid level of 6–10 µmol/L and a postprandial level of 10–14 µmol/L. The meta-analysis by Ovadia et al. of fasting pregnant women with ICP (n = 1726) showed a median level of 23.0 µmol/L (IQR 14.7–41) versus 32.0 µmol/L (IQR 19.0–61.5) in postprandial patients (n = 2795) [68]. Irrespective of fasting and UDCA therapy, various analyses have shown the elevated total serum bile acid level to be a sensitive and specific marker (OR = 4.17, p = 0.0037, AUC = 0.62, p = 0.046) in the diagnosis of ICP and the related adverse perinatal outcome [107, 108].

Furthermore, normal bile acid levels in pruritus do not rule out the diagnosis of ICP, as it can sometimes take weeks for laboratory changes to manifest [3, 56, 79–83, 109, 110]. Follow-up testing is indicated in these cases if unexplained pruritus persists, and bile acid levels should always be considered in the context of the overall clinical presentation.

**STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**

- In fasting blood, the upper reference range of bile acid levels is 6–10 µmol/L and in postprandial blood 10–14 µmol/L.
- Sometimes it may take up to four weeks after the initial pruritus for laboratory results to become abnormal.
- Normal bile acid levels in pruritus do not rule out the diagnosis of ICP.
- Ursodeoxycholic acid medication may yield falsely high values, depending on the assay technique employed.

**Transaminases**

When pruritus is present in ICP, 60% of patients can be expected to develop elevated AST/ALT levels two to thirty times above normal. The elevation in transaminase levels does not correlate with bile acid levels [111–113]. ALT activity is independent of pregnancy and together with corresponding clinical signs can firm up the diagnosis even if there is no bile acid elevation [109, 112].

| Bile duct obstruction (e.g. cholelithiasis)                 | abdominal pain                                              | entire pregnancy       | Liver ultrasonography, MRI                                               |
| Medication, drugs                                           | Pruritus, icterus                                            | at any time            | Medical history, timing of application/abuse and symptoms               |

Hemostasis

ICP does not affect coagulation. In case of pre-existing vitamin K deficiency in the context of steatorrhoea or the administration of bile acid complexing agents (e.g., colestyramine), prothrombin time may be prolonged. This is caused by a decrease in vitamin K-dependent factors (II, VII, IX or X) and thus there is an increased risk of peripartum haemorrhage [56 – 58].

Other laboratory parameters

Elevated direct bilirubin levels are present in up to 20% of cases [57]. Serum gamma GT activity is normal or only moderately elevated, which may be helpful in differential diagnosis. Familial gene mutations, e.g., ABCB4 (MDR3), associated with ICP may present with elevated levels [3, 113, 114]. Due to placental isoenzyme expression with resulting elevated levels, alkaline phosphatase does not play a role in the diagnostic workup of ICP.

Differential diagnoses

▶ Table 2 provides an overview of the various differential diagnoses in ICP, considering the clinical presentation, time of manifestation and their specific characteristics. ▶ Table 3 compares the various manifestations of different parameters in liver disease during pregnancy.

Management of Intrahepatic Cholestasis

Currently, there are no uniform international recommendations for monitoring pregnant women with ICP. Depending on symptom severity, bile acid level and the subjective stress situation of the pregnant woman, both she and her physician should agree on a common goal for the treatment. This also includes setting the timing of delivery against the backdrop of the risk situation, which may have to be readjusted during the pregnancy.

Monitoring the pregnancy

It is unclear how and how often monitoring makes sense, and this is the subject of discussion. Sometimes the laboratory changes only develop with delay. Therefore, follow-up can be useful. If the clinical symptoms are dynamic and TBA ≥ 100 µmol/L, ALT and/or AST > 200 IU/L, laboratory evaluations (bile acids; ALT; AST; gamma GT; bilirubin; and prothrombin time) should be performed more often and, if necessary, inpatient monitoring should be considered. There are no evidence-based follow-up intervals – serial check-ups (e.g., weekly) are not recommended [120].

Rapid, excessive increase or normalisation of the liver enzymes should prompt questioning of the diagnosis of ICP and assessment of possible differential diagnoses.

Ultrasoundography of the liver

Ultrasound imaging of the liver helps in the differential diagnosis (see section on “Differential diagnoses”). There are no specific findings typical of ICP, the bile ducts are unremarkable [115].

RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE

The diagnosis of ICP should be confirmed by determining the following laboratory parameters: bile acids, transaminases, gamma GT, total bilirubin, and prothrombin time.

RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE

Differential diagnosis should include abdominal ultrasoundography, particularly to rule out the possibility of obstructive cholestasis.

Differential diagnoses

Table 3 provides an overview of the various differential diagnoses in ICP, considering the clinical presentation, time of manifestation and their specific characteristics. Table 3 compares the various manifestations of different parameters in liver disease during pregnancy.
Bile acid levels ≥ 100 µmol/L are relevant for treatment (see section on “Delivery timing”). It is unclear whether clinical consequences should also be considered if the levels were initially above the cut-off limits but then were lowered, e.g., with medication. Based on the theory that peak bile acid levels affect outcome, this should be considered when timing the delivery.

The laboratory-specific assay technique is significant when measuring bile acid levels (see section on “Bile acids”). To reduce inaccuracy, UDCA should only be administered after blood has been drawn.

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
It is unclear how and how often pregnant women should be monitored.

RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
Prenatal monitoring should be guided by pre-existing comorbidities and the ICP-specific risk profile in TBA ≥ 100 µmol/L.

RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
During delivery, continuous fetal monitoring should be performed.

Treatment

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
While medication can alleviate symptoms typical of ICP, it does not improve fetal outcome. Giving birth is the only known causal treatment.

Topical agents

Various creams and ointments are used: For example, 2% water-based menthol cream or dimetindene maleate gel may help relieve the itching. Topical treatment does not affect laboratory parameters or perinatal outcome [126].

RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
Topical applications are part of the basic treatment and should be offered to patients.

Ursodeoxycholic acid (UDCA)

UDCA is a naturally occurring bile acid derivative with an anticholestatic effect in the human body. UDCA is commonly used off-label in the treatment of ICP. UDCA has several cholestasis-preventing effects, in particular the induction of hepatic metabolic enzymes and bile acid transporters increases the excretion of bile acids, protects the cholangiocytes of the bile epithelium from the cytotoxicity of bile acids and protects hepatocytes from bile acid-induced apoptosis.

Several prospective randomised trials on the treatment of ICP have been carried out [127–131]. The PITCHES trial, published in

Fetal monitoring

Neither CTG nor Doppler ultrasonography can predict the timing of a possible ICP-specific complication [121]. Therefore, antenatal monitoring is controversial. While CTG changes in ICP have been reported, they are not associated with intraterine fetal death [38]. Stillbirth in ICP is a sudden event without evidence of placental dysfunction. There is no association with either fetal growth restriction or oligohydramnios [3, 82, 84, 109]. Other fetal monitoring techniques, such as amniocentesis and transcervical amniocentesis (for meconium identification in amniotic fluid) [83], fetal electrocardiography [122], fetal percutaneous or amniotic fluid could not adequately explored in studies. Fetal echocardiography with evaluation of the left ventricular myocardial performance index (MPI) offers promising predictive approaches [123–125] but has not yet played a role in standard care.

Even without evident proof of efficacy, regular follow-up is established in clinical routine, mostly by CTG and ultrasonography. Follow-up intervals should be based on pre-existing comorbidities of the mother and the ICP-specific risk profile in TBA ≥ 100 µmol/L. During delivery, continuous fetal monitoring should be performed.

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
Neither ultrasonography/Doppler ultrasound nor cardiotocography are able to predict stillbirth in ICP patients. Evidence-based follow-up intervals therefore do not exist.
2019, aimed to prevent stillbirths by UDCA medication. 605 pregnant women with ICP were prospectively randomised in double-blind fashion to the study arm UDCA (initial 2 × 500 mg daily) or placebo. The UDCA group demonstrated an improvement in pruritus and ALT levels. Compared to placebo, UDCA treatment did not improve the combined perinatal outcome (neonatal mortality, preterm birth, NICU admission): 23 vs. 27% (RR 0.85; 95% CI 0.62–1.15). However, the total number of stillbirths (n = 3) in the trial was rather small [127]. The strict induction policy of the trial, conducted in England and Wales, from 37 + 0 weeks gestation may have contributed to this [57]. A secondary subgroup analysis could not identify any cohort in whom UDCA significantly reduced TBA levels or pruritus [132]. The analyses did not consider which dose of UDCA each pregnant woman had taken and over which period, which considerably weakens the significance [133]. A Cochrane review published in July 2020 on the use of UDCA in ICP highlights the benefit in reducing pruritus, but not in preventing stillbirth or spontaneous preterm birth [126]. However, there are the following trends in perinatal outcome with UDCA compared to placebo:

- IUFT/stillbirths: RR 0.33 (95% CI 0.08–1.37; 6 trials, n = 955).
- Transfer to NICU: RR 0.77 (95% CI 0.55–1.08; 2 trials, n = 764).
- Spontaneous preterm birth: RR 0.78 (95% CI 0.49–1.23; 3 trials, n = 749).
- Spontaneous and iatrogenic preterm births: RR 0.60 (95% CI 0.37–0.97; 3 trials, n = 819).

In addition to the perinatal effects, long-term effects are also suspected. For example, it has recently been shown that treatment with UDCA has a favourable effect on fetal lipid metabolism [134]. UDCA treatment is safe and has few side effects [127]. The latter are limited to gastrointestinal symptoms ranging from pasty stools to diarrhoea [135]. The initial oral dose usually is 3 × 250 mg or 2 × 500 mg. Dosing may be adjusted depending on the maternal symptoms. The maximum UDCA dose often administered in trials is 2000 mg. In this context it is used off-label. Dosage recommendations vary and are mostly 10–15 mg/kg bw [104, 127].

**STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**

Ursodeoxycholic acid can improve both maternal symptoms and liver function in ICP. According to current evidence, the therapy does not change the perinatal outcome.

**RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**

If pruritus persists during UDCA therapy, additional administration of rifampicin may be considered in individual cases.

**Colestyramine**

As an anion-exchange resin, colestyramine prevents the reabsorption of bile acids in the enterohepatic circulation. The sequel of this malabsorptive treatment is steatorrhea with excretion of fat-soluble vitamins. Decreased vitamin K levels may result in significant peripartum bleeding complications in mothers and neonates [141]. A trial with 84 pregnant women comparing UDCA with colestyramine revealed that the anion exchange resin was inferior in all outcome parameters (reduction of pruritus, bile acids and AST/ALT) and worse tolerated (29% nausea/vomiting/diarrhoea vs. 0% adverse events in the UDCA group) [142]. Because of the mechanism of action, combined treatment with UDCA is counter-productive in terms of the pharmacokinetics.

**S-Adenosyl-L-methionine (SAMe)**

SAme is metabolised in the liver, among other organs, and serves as a methyl group donor in the biosynthesis of phospholipids for the excretion of oestrogen metabolites [143, 144]. In animal models, SAMe has been shown to reduce cholestasis; the exact mechanism of action is unclear [145]. Studies on SAme in pregnant women with ICP as a single agent or additive with a dosage of
400–1600 mg per day did not demonstrate clinical superiority to treatment with UDCA alone [131, 146 – 148].

**RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**
At this stage, SAMe cannot be recommended in the treatment of ICP.

**Dexamethasone**
Three observational studies found improvement in symptoms and laboratory parameters with dexamethasone in the treatment of ICP [149 – 151]. In a prospective randomised trial comparing oral dexamethasone dosed at 10–12 mg/d with UDCA, no therapeutic benefit was seen [128]. In addition, there are considerable concerns about long-term effects in the child with repeated high doses [152].

**RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**
Treatment for ICP should not include systemic dexamethasone.

**Antihistamines**
The use of antihistamines in ICP has not been tested in clinical trials but appears to provide symptomatic relief of pruritus – the extent to which a sedative side effect has any effect in this regard is unknown [126].

Tremors and diarrhea have been observed in the neonates with long-term administration of some first-generation H1 antagonists (chlorpheniramine, diphenhydramine, hydroxyzine). These side effects have not yet been reported with the agents clemastine (1st generation) and cetirizine (2nd generation) more commonly administered in Germany [153].

**RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**
Systemic use of antihistamines in the relief of pruritus may be considered.

**Other treatment approaches**
In severe refractory pruritus, endoscopic placement of a nasobiliary tube, MARS (Molecular Adsorbent Recirculating System) therapy or plasmapheresis can provide short-term and effective relief of itching [154]. Due to inadequate studies, there is no evidence of efficacy for other treatment options such as UV light, herbal remedies and phenobarbital.

**RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**
In rare severe individual cases with marked maternal symptoms, invasive procedures may be useful to prolong the pregnancy after standard therapy aiming at symptom improvement has been exhausted.

**Delivery Management**

**Delivery timing**
When deciding on the time of delivery, it is important to weigh the risk of IUFT against iatrogenic prematurity with its consequences for the neonate [155, 156]. The bile acid level plays a decisive role as a predictive marker for stillbirth and neonatal complications. In trials its cut-off level ranges from > 40 µmol/L to ≥ 100 µmol/L [68, 74 – 76]. In the trial with the highest evidence level by Ovadia et al. in 5269 women with ICP, the rate of stillbirth in bile acid levels ≥ 100 µmol/L increases significantly from 34 + 0 weeks of gestation to a prevalence of 3.44%, which is a more than 30-fold increase in the risk compared with the < 40 µmol/L group (HR 30.5; 95% CI 8.83–105.3) (Figs. 2 and 3). In contrast, the risk of stillbirth for bile acid levels of 40–99 µmol/L and < 40 µmol/L does not differ significantly compared to healthy pregnant women and has a prevalence of 0.28% and 0.13%, respectively [67, 68].

Prospective randomised clinical trials on the issue of optimal time of delivery in ICP are lacking. In a retrospective British study, Williamson et al. found 23 (7%) IUFTs among the 352 patients analysed. In singleton pregnancies, IUFTs occurred at a median of 38 + 0 weeks of gestation; in the three gemini pregnancies before 37 + 0 weeks of gestation [77].

The PITCHES trial compared treatment with UDCA versus placebo and reported three (0.5%) IUFTs among the 604 patients with ICP analysed [127]. Here, the delivery management of the patients followed routine care. Since this trial was conducted in the United Kingdom, it was based on the NICE guideline, which recommends delivery from 37 + 0 weeks of gestation Thus, the median gestational age at delivery in the PITCHES trial was 38 weeks of gestation, which may have contributed to a reduction in the rate of IUFT. Since in this trial the bile acid levels were only moderately elevated in most patients, this was more of a low-risk ICP population.

**STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE**
A bile acid level ≥ 100 µmol/L is a predictive marker for stillbirth and neonatal complications. The time during pregnancy at which the bile acid levels should be determined is not defined.
Fig. 2 Number of singleton pregnancies with ICP (blue columns) and percentage with IUFT (red columns), by bile acid level. IUFT prevalence by bile acid group (<40 µmol/L, 40–99 µmol/L and ≥100 µmol/L) is shown in the graph above (data from [68]).

Fig. 3 Kaplan-Meier graph – percentage of foetuses with IUFT between 24 and 40 weeks of gestation in singleton pregnancies with ICP (data from [68]).
STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
The decision to deliver is based on weighing the risk of intrauterine fetal death against iatrogenic preterm morbidity and mortality.

RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
Bile acid levels in maternal blood should be part of the decision-making process regarding the best time of delivery. The time of delivery is determined individually, in a shared decision-making process with the expectant mother.

RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
Analogous to the German AWMF S2k guideline Induction of labour (expert consensus) [157]:
≥ 100 µmol/L:
• induction of labour may be recommended between 34 + 0 and 36 + 6 weeks of gestation.

< 100 µmol/L:
• induction of labour should be recommended at 37 + 0 weeks of gestation.
• induction of labour must be recommended at 38 + 0 weeks of gestation.

Delivery modality
In their retrospective study, Wickström Shemer et al. analysed 25 780 births to determine the risk of emergent caesarean section after active induction management in ICP between 37 + 0 and 39 + 0 weeks of gestation. Of these, 231 women with ICP gave birth during this period. When labour started spontaneously, women with ICP had the same rate of emergent caesarean section (aOR, 1.33; 95% CI 0.60–2.96) and were less likely to undergo emergent caesarean section after induction of labour (aOR, 0.47; 95% CI 0.26–0.86) compared with non-ICP expectant mothers. There was no difference in the risk of fetal asphyxia [158]. Another retrospective case-control study of 64 inductions of labour due to ICP revealed no increased risk of vaginal surgical delivery or caesarean section. Other complication rates, e.g., for postpartum haemorrhage, were comparable to the control group of induced labour without ICP [159].

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
Induction of labour for ICP between 37 + 0 and 39 + 0 weeks of gestation is not associated with an increased risk of caesarean section or operative vaginal delivery.

Postpartum Management and Follow-up
The laboratory and clinical changes normalise completely postpartum. In case of persistence beyond a period of 4–8 weeks, the diagnosis of ICP should be questioned.

There is a high rate of recurrence of up to 70% in subsequent pregnancies [47]. Transient recurrent symptoms may also occur in reproductive stimulation treatment; treatment can then take place in the natural or modified natural cycle. In addition, the risk of cholestasis is also increased outside pregnancy. Oestrogen-containing drugs such as contraceptives can cause ICP-like symptoms. With gestagen-only preparations (systemic or IUD), the risk is low [160].

New evidence suggests an increased risk of developing various liver, biliary, pancreatic, metabolic, and immune-mediated disorders. It remains unclear whether pregnancy activates the disease cascade or whether these disorders were already present subclinically before pregnancy [10, 30,64, 65].

The hazard ratios for subsequent hepatobiliary disease after initial diagnosis of ICP is 2.62 (95% CI 2.47–2.77) with a cumulative annual increase of ~ 1%. In addition, following ICP the risk is highest for the diagnosis of chronic hepatitis (HR 5.96, 95% CI 3.43–10.33), liver fibrosis/cirrhosis (HR 5.11, 95% CI 3.29–10.33), hepatitis C (HR 4.16, 95% CI 3.14–5.51) and cholangitis (HR 4.22, 95% CI 3.13–5.69) [30].

The presence of heterozygous, disease-associated ABCB4 variants favours hepatobiliary sequelae [161]. If genetic testing has detected certain ABCB4 variants, lifelong UDCA administration and annual ultrasound studies (elastography if necessary) and monitoring of laboratory parameters are recommended. Information about the increased incidence of sequelae is mandatory.

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
The laboratory and clinical changes normalise completely postpartum. Subsequent pregnancies are at elevated risk of recurrence. Outside of pregnancy, the risk of hepatobiliary disorders is increased. Life expectancy is not affected.

STATEMENT BY THE WORKING GROUP ON OBSTETRICS AND PRENATAL MEDICINE
The administration of oestrogen-containing preparations is based on a risk-benefit analysis. Gestagen-only medications are appropriate for contraception after ICP.
RECOMMENDATION BY THE WORKING GROUP ON OBSTETRICS AND PREGNATAL MEDICINE

Women with ICP should be informed about the increased risk of developing sequelae. Liver enzymes, especially the transaminases, should be monitored after 6 weeks at the latest. In the case of persistently elevated transaminase levels, the patient should be seen by a hepatologist. More detailed regular follow-up intervals should be scheduled on an individual basis.
