The role of pancreatoscopy in the diagnostic work-up of intraductal papillary mucinous neoplasms: a systematic review and meta-analysis

INFOGRAPHIC

What is the role of pancreatoscopy for IPMN?

- Limited accuracy of diagnostic imaging (CT, MRI, EUS, ERCP)
- Risk of over- or undertreatment

Methods: Meta-analysis: 25 articles

Introduction
Intraductal papillary mucinous neoplasm (IPMN) is a common precancerous lesion of the pancreas, characterized by intraduc-
tal papillary proliferation of mucin-producing cells, resulting in
cystic dilatation of the pancreatic duct (PD) [1, 2]. IPMN may
progress from adenomatous lesions to high grade dysplasia
(HGD) and finally to invasive carcinoma. Branch-duct IPMN
(BD-IPMN) is the most prevalent subtype. Main-duct IPMN
(MD-IPMN) is however associated with the highest risk of pro-
gression to malignancy and is considered an indication for sur-
gery if the main PD (MPD) diameter is > 10 mm, or if there is evi-
dence of jaundice or mural nodules [3, 4]. Early identification of
MD-IPMN is important to allow surgery to be performed before
the development of cancer.

Currently, imaging modalities used for the diagnosis of IPMN
include computed tomography (CT), magnetic resonance ima-
ging (MRI), and endoscopic ultrasonography (EUS). Even with
the addition of endoscopic retrograde cholangiopancreatogra-
phy (ERCP) and ERCP-guided brushing, the diagnosis of MD-
IPMN and BD-IPMN can be challenging, as is determining the
presence of HGD or invasive carcinoma. As a result, some pa-
tients undergo unnecessary pancreatic surgery for IPMN with
low grade dysplasia (LGD) or benign cystic lesions [5]. In addi-
tion, when surgery is indicated, preoperative determination of
the extent of MD-IPMN using these techniques can be difficult.
This could result in either unnecessary loss of pancreatic tissue
in the case of an overly extensive resection, or progression of
disease in the case of an incomplete resection. Although intra-
operative frozen section analysis of the resection margin is rou-
tinely performed during pancreatic surgery, this strategy does
not account for discontinuous “skip” lesions [6].

Over the past decades, peroral pancreatoscopy (POP) has
been used more frequently in the diagnostic work-up of pan-
creaticobiliary disorders. It has potential additional value for
the diagnosis of IPMN and in determining the intraductal extent
of the lesion. Moreover, intraoperative pancreatoscopy (IOP)
can assess residual skip lesions [7]. However, the exact role of
POP in the diagnosis and treatment of IPMN is unclear. There-
fore, this systematic review and meta-analysis aimed to sum-
machine the current literature on the technical success, safety,
diagnostic yield, and clinical utility of POP in the management
of IPMN.

Methods
Eligibility criteria
Studies eligible for inclusion were randomized controlled trials,
prospective and retrospective cohort studies, and case series.
Case reports, reviews, poster abstracts, and studies in a lan-
guage other than English were excluded. Studies examining
adults with a (suspected) diagnosis of IPMN, undergoing POP,
either performed during diagnostic work-up for IPMN or perio-
operatively, were deemed eligible.

Search strategy and study selection
On 11 February 2022, according to the PRISMA guidelines (Ta-
ble 1s, see online-only Supplementary material), a systematic
literature search was performed in EMBASE, Medline Ovid,
Web of Science, Cochrane CENTRAL, and Google Scholar. Pre-defined keywords used in this search were “pancreatoscopy” and “IPMN” to identify relevant articles. The full search strategy is presented in Table 2s.

After duplicates of the retrieved articles had been removed, the titles and abstracts were independently screened for eligibility by two authors (D.d.J. and P.S.). The full text of potentially relevant articles was retrieved and independently assessed. Disagreement was resolved by consensus after discussion with a third author (P.J.d.J.). The references listed within the selected articles were screened to identify additional studies relevant for inclusion in this literature review.

Data extraction

Data were systematically extracted from all included studies using a predefined standardized form. Data extracted included study design, patient characteristics, and intervention-related characteristics (e.g. successful cannulation and the ability to visualize the target area). In addition, any pancreatoscopic visual characteristics of IPMN that were reported in the articles, the use and diagnostic value of adjunctive modalities such as NBI, and the effect of POP findings on clinical management were noted.

The evaluated outcomes were: (i) technical success, defined as the ability to advance the pancreatoscope to the target area/lesion within the MPD, and safety, including adverse events (AEs) such as post-ERCP pancreatitis (PEP), perforation, and bleeding; (ii) diagnostic pancreatoscopic features and accuracy, defined as the rate of agreement between these features and pathological examination of the surgical or autopsy specimens, for both POP visualization alone and for POP-guided biopsy or cytology; and (iii) the effect on clinical decision-making, defined as the surgical approach being altered on the basis of the pre- or intraoperative pancreatoscopic findings.

Statistical analysis

Statistical analyses were mostly limited to descriptive statistics using frequencies and percentages. For the pooled AE rate, meta-analysis was performed using R version 4.0.1 with the “meta” package. Random-effects meta-analysis was used, regardless of the results of heterogeneity testing. The effect size can vary per study because of differences in cohorts and the included patients, therefore random-effect meta-analysis is more suitable than fixed-effects meta-analysis. Data are presented as means with 95% CIs. Sensitivity analysis was performed for studies that reported the AEs on patients with IPMN only and for POP-guided biopsy or cytology; and the effect on clinical decision-making, defined as the surgical approach being altered on the basis of the pre- or intraoperative pancreatoscopic findings.

Results

A total of 25 articles met the inclusion criteria [8–32]. The process of article selection and reasons for exclusion are summarized in Fig. 1. The data extracted from the included studies are summarized in Table 1 and Table 2. There were 22 studies that primarily reported on the diagnostic yield of POP for all IPMN types [8–19, 21, 22, 24–30, 32] and 11 articles that reported on the effect of the POP findings, in the preoperative and/or intraoperative setting, on clinical decision-making (i.e. choice to proceed to surgery and extent of surgery) [10, 13, 14, 19, 21–24, 28, 29, 31].

Technical success and adverse events

In all studies, technical success rates were reported, defined as the ability to advance the pancreatoscope into the MPD. This cannulation rate ranged from 86% to 100% [8–32]. Pancreatoscopy was performed for diagnosis of a suspected MD-IPMN, BD-IPMN, or mixed-type IPMN (MT-IPMN). A dilated MPD was not required. Predictive factors reported for successful cannulation were a dilated MPD or a wide papillary orifice. It was not often reported how many patients underwent papillotomy prior to or during the POP procedure; however, where reported, it ranged from 0% to 92.7%. One study reported that POP was successfully performed via the minor papilla in four patients [20].

After successful cannulation, the rate of adequate visualization of the PD and region of interest ranged from 60% to 100%, but the specific location of the lesion in the PD was often not described. Of the 25 included studies, only six reported an observation rate lower than 100% [11, 12, 19, 22, 25, 26], resulting in a combined observation rate of 95.6%. Reasons for the inability to visualize the target area were: inadequate clearance of mucus; a nondilated MPD; and concomitant anatomical features, such as a ductal stricture. Abundant mucus impaired vis-

¹ Calculated over the total group of patients and not in patients with IPMN only.

² Calculated per pancreatoscopy procedure, not per patient.
ual characterization of the IPMN or wall of the MPD, despite flushing [12, 25]. Visualization of BD-IPMN was more difficult as compared with MD-IPMN, mainly owing to more difficult angulation of the pancreatoscope in reaching the area of interest and the smaller diameter of the MPD [11, 12, 22].

The occurrence of AEs was reported in 17 out of 25 studies [9, 11, 13–16, 18–22, 25–29, 31]. The overall pooled AE rate of these 17 studies was 12% (95% CI 9%–17%) (Fig. 2). PEP was the most common AE, with a pooled incidence rate of 10% (95% CI 7%–15%) [11, 13–15, 20–22, 26–29] (Fig. 1a). The severity of PEP was mild in 24 patients (70.6%), moderate in seven (20.6%), severe in two (5.9%), and unknown in one (2.9%). One patient with severe PEP died [21].

In reporting AE rates, three studies did not make a difference between patients with and without (suspected) IPMN and therefore the reported overall AE rate and PEP rate might differ for patients with IPMN, albeit sensitivity analysis showed no significant difference between these [15, 20, 26]. Most studies did not elaborate on the MPD diameter in relation to PEP. Trindade et al. reported that PEP occurred more frequently in patients with a focally dilated MPD (n = 7/18; 39%) compared with patients with a diffusely dilated MPD (n = 1/13; 8%; P = 0.05) [29]. In addition, Arnelo et al. reported that 6/7 patients diagnosed with PEP had a normal or only slightly dilated MPD [21]. Other AEs included post-sphincterotomy bleeding (1.3%) [26], a mild sedation-related event (3.2%) [29], and cholangitis (8.3%) [22].

### Visual diagnosis of IPMN and detection of high risk features by POP

Pancreatoscopic characteristic features of IPMN were intraductal papillary or villous projections, and the presence of mucus [33]. Other features included: intraductal fish-egg-like lesions, that were sometimes seen on a protruding lesion, and granular mucosa [8, 9, 11–16, 18, 19, 22, 24–26, 28–30]. However, not all classical features are consistently seen. For example, in patients with a radiological diagnosis of MD-IPMN, the classical features of IPMN, such as a fish-eye papilla and oozing of mucus from the papilla, were detected in only 35% of patients in whom MD-IPMN was confirmed by histology [21]. Examples of some of the visual characteristics of IPMN seen on POP can be found in ▶ Fig. 3 and ▶ Video 1 and ▶ Video 2.

Seven studies reported on the sensitivity, specificity, and overall diagnostic accuracy rates of POP in the visual diagnosis of IPMN [10, 13, 16, 21, 25, 27, 30]. In these studies, the results

**Heterogeneity:** $I^2 = 19 \%, \tau^2 = 0.1129, P = 0.23$

**Fig. 2** Pooled AE rate for all studies that reported adverse events.

**Fig. 3** Example images during peroral pancreatoscopy (POP) in four patients with intraductal papillary mucinous neoplasm (IPMN) showing:

- a: a clear proximal margin of a main-duct IPMN (MD-IPMN) that was suspicious for malignancy, but was found to be a mixed-type IPMN without any malignancy on pancreatoduodenectomy (see also ▶ Video 1);
- b: a clear image of a visible polypoid lesion in the setting of MD-IPMN, with biopsy revealing focal malignant transformation;
- c: the clear fish-egg-like lesions in an MD-IPMN;
- d: a very wide side branch in the body of the pancreas, with a nodular mass seen at the opening of the side branch, which showed mild dysplasia on POP-guided biopsy and later pancreatoduodenectomy.
of POP were compared to pathology results after resection or from biopsies, or the absence of progression during long-term follow-up. Reported sensitivity rates ranged between 64% and 100% [10,13,16,21,27,30], specificity rates between 75% and 100% [13,21,27,30], and overall diagnostic accuracy between 87.5% and 100% [10,13,25].

The ability to differentiate noninvasive and malignant MD-IPMN with POP has been investigated in eight studies [8,10–12,14–16,26]. The visual classification system proposed by Hara et al. allowed for discrimination of malignant IPMN from noninvasive IPMN with an accuracy of 88% for MD-IPMN and 67% for BD-IPMN [14]. Pancreatoscopic findings that were more frequently observed in patients diagnosed with malignancy were a coarse mucosa, friability, and tumor vessels [12,15,16]. Another important finding by Trindade et al. was that 13 patients (42%) had additional high risk features on POP that were not seen on imaging or EUS, for example papillary projections, nodules, and in one patient a frank mass [29].

Additional imaging modalities, such as narrow-band imaging (NBI) using the Olympus CHF-BP260, have been evaluated in three studies [17–19] and are described in Appendix 1s. The diagnostic value of targeted biopsies, cytology, and pancreatic juice collection are presented in Table 1 and Appendix 2s.

**Effect on clinical decision-making**

Eleven articles reported on the pre- or intraoperative assessment of the intraductal extent of IPMN by pancreatoscopy and the effect of its findings on clinical management [10,13,14,19,21–24,28,29,31].

In four studies, the resection line was based on preoperative POP findings [13,14,19,29]. Atia et al. reported that POP correctly identified and located IPMN in 4/4 patients with a final diagnosis of IPMN (100%) and correctly identified a pancreatic cyst in a further patient [13]. In another study, the resection margin was based on preoperative POP and intraductal sonography, and comparison with postoperative surgical specimens revealed only one positive resection margin (2.5%) [14]. Miura et al. used POP with NBI to determine the extent and resection line in seven patients, with postoperative examination showing no tumor in the excision stumps [19]. In a study by Trindade et al., POP dictated the surgical plan determined prior to POP in 42% of patients with MD-IPMN (13/31) [29]. This was more common in those with a diffusely dilated MPD > 10 mm (10/31; 77%) compared with those with a focally dilated MPD (3/18; 17%; P = 0.001).

Five studies investigated whether pre- or intraoperative pancreatoscopy findings altered the intended surgical approach, which was based on cross-sectional imaging, ERCP, and/or EUS [10,23,24,28,31]. After initial transection, IOP was performed to check the remaining PD for lesions. For POP, it was not clearly reported how the additional margin was determined. Overall, determination of the extent of the lesion or identification of skip lesions by visualization or biopsy resulted in an altered surgical approach in 13%–62% of patients: in 13%–31% of patients, it resulted in a more extensive surgical resection [10,23,24,28,31]; in 6%–31% of patients, it resulted in a less extensive surgical resection [23,24,31]. Two studies reported that preoperative POP findings affected clinical decision-making or determination of the excision line, without reporting the initial surgical plan [21,22]. The specifics of these studies can be found in Table 2 and Appendix 3s. Complications related to IOP were not reported.

"Video 1" A clear demarcation of the proximal and distal margins of a suspected main-duct intraductal papillary mucinous neoplasm (IPMN) is shown in a case that proved to be a 4-cm mixed-type IPMN without any malignancy at pancreatoduodenectomy.

Online content viewable at: https://doi.org/10.1055/a-1869-0180

"Video 2" A main-duct IPMN is delineated and peroral pancreatoscopy-guided biopsies are taken, which subsequently showed an IPMN without dysplasia, while at surgery, a main duct IPMN with low grade dysplasia was identified.

Online content viewable at: https://doi.org/10.1055/a-1869-0180
Discussion

The risk of malignancy in IPMN is highly variable as BD-IPMNs contain malignancy in a minority of patients, while MD-IPMNs have a higher reported incidence of malignancy [3,4]. Although the general recommendation of the International Association of Pancreatologists and others is that mucin-producing neoplasms with high risk features or MD-IPMN > 10mm should undergo surgical resection, obtaining a definite diagnosis and assessing the possible intraductal extent can often be difficult. As such, the primary utility of POP in IPMN is considered three-fold: (i) to confirm the diagnosis in equivocal cases based on imaging and history, especially when there is a question of chronic pancreatitis versus IPMN; (ii) to assess the presence of malignancy or high grade dysplasia; and (iii) to map the IPMN in order to guide resection margins. In current clinical practice, the exact role of POP remains to be determined. Its use remains limited to large volume referral centers, and available data regarding its efficacy and safety are limited and heterogeneous. In this meta-analysis, we summarize the available data on the use of POP in patients with (suspected) IPMN. Following a strict predefined search strategy, we identified 25 articles eligible for inclusion.

Overall, cannulation of the MPD with the pancreatoscope was successful in the vast majority of patients in whom standard MPD access had already been achieved (86%–100%), and adequate visualization of the target area could be achieved in 60%–100% of patients, with the vast majority of studies reporting success rates of 100%. Predictive factors reported for failure to reach the target area were: impaired visibility due to an abundance of mucus; anatomical features such as strictures; or a nondilated MPD [11,12,22,25].

Despite these high technical success rates, AEs occurred in 12% of patients [11,13–15,20–22,26–29]. Because the indication for pancreatoscopy is only diagnostic, the risk of complications may more readily outweigh the benefit of the procedure in comparison with therapeutic procedures. An acknowledgement of the high risk of pancreatitis is of clinical relevance because it may lead to postponement or even deferral of surgery. However, in the majority of the patients, PEP was treated conservatively and its severity was mild to moderate. The most important risk factor for PEP in the evaluated studies was the presence of a focally or mild-to-nondilated MPD, as compared with patients with a diffusely widened MPD, in whom the incidence of PEP was lower [21,29]. All this should be interpreted in light of the observation that preoperative pancreatoscopy influenced the type/extent of surgery in the vast majority of patients with a diffusely dilated MPD, but only in less than 20% of those with a focally dilated MPD [29].

Several studies have investigated the different pancreatoscopic features that are consistent with benign and malignant IPMN [8,10–12,14–16,26]. Features that were more frequently identified in patients diagnosed with malignant IPMN were intraductal fish-egg lesions, prominent vascular changes, villous projections, and vegetative projections. Also, friability and a coarse mucosa were described as being related to malignancy. In addition, three studies investigated the additional value of NBI in the assessment of intraductal lesions and showed promising results, with improved visualization of the vasculature and flat lesions, along with identification of skip lesions that were otherwise not detected [17–19]. Subsequently, identification of these areas could improve the yield of intraductal (targeted) biopsies.

Unfortunately, there are no studies available that have investigated the interobserver agreement of the different pancreatoscopic features and therefore their exact clinical value remains unclear. Sethi et al. previously showed that interobserver agreement of visual assessment of indeterminate biliary strictures is very low, even among experienced endoscopists [34]. It is likely that this would be the case for IPMN as well.

Considering the moderate sensitivity and specificity rates reported in this review for a visual diagnosis of IPMN (64%–100%, and 75%–100%, respectively), histological confirmation remains important. The yield of POP-guided targeted biopsies and/or cytology was reported in eleven studies with widely varying results, with sensitivity rates ranging from 13% to 100% and specificity rates ranging from 53% to 100% [11,14,16,21,22,25–29,32]. This variation can be explained by the small biopsies obtained via POP, owing to difficult maneuvering of the biopsy forceps, which make pathological diagnosis difficult. With regard to cytology examination, different sampling methods were used and different rates were reported for irrigation fluid compared with pancreatic juice obtained via POP. Interestingly, two studies showed that samples obtained by POP showed higher diagnostic accuracy rates than samples obtained by a catheter [22,32].

To improve the diagnostic yield of POP-guided targeted biopsies and cytology, future studies are needed to investigate the best collection method of fluid for cytology examinations and biopsy samples. To further optimize the yield of POP, there are some studies that have indicated that probe-based confocal laser endomicroscopy might be helpful in determining the nature of pancreatic lesions, such as IPMN, and its clinical management [35,36].

The most important question in the setting of pancreatoscopy as a complementary diagnostic tool in the work-up of IPMN is its actual impact on clinical (therapeutic) management and patient outcomes. Results varied greatly between the studies, from only 13% of patients having their surgical approach altered to almost all patients being impacted [10,13,14,19,21–24,28,29,31]. In some studies, POP detected multifocal lesions that were otherwise not detected or could have been mistaken for chronic pancreatitis [10,20–37]. The nature of the included studies makes it difficult however to determine the exact role of POP in the preoperative diagnostic work-up. Ideally, the primary utility of POP in IPMN would be to confirm the diagnosis of IPMN in persistent equivocal cases, or to map the extent of the IPMN where there is uncertainty regarding the extent of surgery. However, it should preferably only be performed after a diagnostic work-up including imaging (CT and/or MRI) and EUS with tissue acquisition, and following a multidisciplinary meeting. The Fukuoka guidelines advise performing EUS if there are worrisome features present on cross-sectional imaging [4]. However, the yield is relatively low with a pooled sen-
The role of peroral pancreatoscopy (POP) in the preoperative evaluation of intraductal papillary mucinous tumor of the pancreas (IPMN) has been a subject of interest for many years. However, despite the reasonably high diagnostic accuracy rates that have been reported, the exact role of POP in the diagnostic work-up of IPMN remains unclear, mostly because of methodological shortcomings and heterogeneity between studies. Large multicenter consecutive prospective studies performed according to a predefined protocol, including well-described procedural aspects, imaging documentation (preferably by video), and the application of intraductal pancreatoscopy-guided biopsies, are needed to better define the role of POP in the diagnostic algorithm of IPMN.
