Gastroduodenal ulceration following liver radioembolization with yttrium-90

Radioembolization or selective internal radiation therapy (SIRT) with yttrium-90 ($^{90}$Y) resin microspheres is an effective locoregional treatment for unresectable primary and metastatic malignancies of the liver [1]. SIRT is a straightforward method of delivering microspheres containing $^{90}$Y (a high-energy $\beta$-emitting radioisotope) to the microvasculature of malignancies whilst sparing the normal liver parenchyma.

A 54-year-old woman with unresectable bilobar liver metastases from a rectal adenocarcinoma was recommended to undergo $^{90}$Y-SIRT. Pretreatment hepatic angiography revealed normal arterial anatomy (Fig. 1). The gastroduodenal artery was embolized with eight coils to prevent nontargeted flow to the stomach and duodenum. Afterwards a $^{99}$Tc-macroaggregated albumin solution (to simulate the $^{90}$Y microspheres) was selectively injected into the hepatic artery. This was followed by a single-photon emission computed tomography (SPECT) scan, which excluded extrahepatic shunting into the gastrointestinal tract and the lung. $^{90}$Y-SIRT was performed 2 weeks later. Selective catheterization of the left and right lobes of the liver permitted delivery a 1.7 GBq dose of $^{90}$Y resin microspheres. A post-treatment SPECT scan confirmed uptake in the liver only (Fig. 2).

The patient presented again having developed epigastric pain 12 weeks after undergoing the $^{90}$Y-SIRT. An upper gastrointestinal endoscopy showed a large gastric ulcer at the antrum and a superficial ulcer in the duodenal bulb (Fig. 3). Biopsies revealed deep purple, round, acellular foreign bodies, compatible with $^{90}$Y resin microspheres (Fig. 4). Esomeprazole (40mg twice daily) was started and produced a gradual clinical improvement.

Radioembolization-associated gastroduodenal ulceration results from nontargeted flow of microspheres through inter-relat-
ed gastrointestinal tract blood vessels that may sometimes be obscured in liver angiograms despite a detailed pretreatment hepatic angiographic study. The literature reports gastrointestinal complications rates from SIRT of 3%–24% [2], with complications resulting from direct radiation toxicity rather than ischemia [3].

A high degree of suspicion is required to make this diagnosis because there are no specific clinical or endoscopic features. Definitive diagnosis is made pathologically by visualization of the pathognomonic microspheres. Treatment with high-dose proton pump inhibitors is recommended, although a response rate under 50% is to be expected [2, 4].

Fig. 4 Histological appearance of the biopsy specimens stained by hematoxylin and eosin (H&E) showing extensively ulcerated antral gastric mucosa with granulation tissue and the presence of numerous 90Y resin microspheres in the lamina propria. Scattered residual gastric glands showing marked cytological atypia are also present.
