A 43-year-old man was admitted to our hospital for polypectomy because of multiple colonic polyps. He had no history of hemorrhage or abdominal trauma, and was not being treated with anticoagulant therapy. His laboratory results, including coagulation testing, were all normal. A ball-like polyp was identified in the descending colon (Fig. 1a) and was removed using a snare to leave a 10-mm peduncle. The remaining four small polyps (≤5 mm), located in the sigmoid colon and rectum, were removed using forceps.

The following morning, the patient ascended and descended a staircase for approximately 40 minutes. He later complained of having passed bloody stools, with a volume of approximately 150 mL, 32 hours after the polypectomy. We performed another colonoscopy and found bleeding at the site of the peduncle in the descending colon. Three clips were placed to stop the bleeding (Fig. 1b).

Later the same day, 40 hours after polypectomy, the patient again passed bloody stools, so we immediately performed a third colonoscopy. During this procedure we observed an intramural hematoma (70 × 50 × 40 mm) near the site of the peduncle (Fig. 1c) and noted that the surrounding mucosa was ruptured and bleeding. We therefore injected 10 mL of 1:2000 epinephrine into the hematoma and two clips were used to repair the rupture. Following treatment, the hematoma reduced in size and the bleeding ceased (Fig. 1d). The patient was kept under observation for 3 days until he passed normal-colored stools.

Significant intramural hematoma can occur in any part of the gastrointestinal tract [1]. The small bowel, particularly the duodenum, is the site most frequently involved; however intramural hematoma of the colon is a relatively rare event [2]. Spontaneous intramural hematomas are often the result of blunt trauma [3]. The typical causes of nontraumatic spontaneous hematoma are blood dyscrasia, anticoagulant therapy, and other hematologic diseases. Intramural hematoma after polypectomy is rarely observed.
