A previously well, 62-year-old woman was referred to our emergency department with a 1-week history of fever, abdominal pain, and passing loose stool. On arrival, she was found on physical examination to have tenderness in the upper abdomen. The results of her laboratory tests showed a white blood cell count of $11.3 \times 10^9/L$ (normal $3.5 - 11.0 \times 10^9/L$) with eosinophils of $5.6\%$ (normal $1\%-5\%$). Abdominal ultrasound and computed tomography (CT) scans revealed diffuse wall thickening in the ascending and transverse colon (Fig. 1). Colonoscopy showed diffuse hyperemic patches extending from the cecum to the transverse colon (Fig. 2). Esophagogastroduodenoscopy revealed multiple tiny whitish nodules in the second portion of the duodenum (Fig. 3).

Histopathological examination of biopsy specimens taken from the abnormal areas of the colon showed intact mucosa with filiform larvae of *Strongyloides stercoralis* in the lamina propria (Fig. 4a). Biopsy specimens from the duodenum revealed adult female worms (Fig. 4b, c) and rhabditiform larvae (Fig. 4b, d) of *S. stercoralis* in the crypts of the duodenal mucosa. Larvae of *S. stercoralis* were also found on examination of the stool. The patient was therefore diagnosed as having gastrointestinal strongyloidiasis and she was treated with a single dose of ivermectin (200 μg/kg). Follow-up endoscopy 1 month later showed normal-looking mucosa in both the duodenum and colon, and histopathological examination of repeat biopsy specimens taken from duodenum and colon revealed no evidence of parasites.

The most common gastrointestinal symptoms of strongyloidiasis include nausea, vomiting, abdominal pain, and diarrhea [1, 2]. The right-sided colon is involved in most patients. Endoscopic findings in strongyloidiasis are numerous and include loss of vascular pattern, erythema, erosions, ulcerations, and the presence of yellowish-white nodules [1, 3].

In the normal life cycle, free-living filiform larvae enter the skin and the parasitic life cycle begins. The larvae enter the venous circulation, are transported to the lungs, penetrate the alveolar spaces, and are expectorated and swallowed. They arrive at the duodenum, where they mature into adult females and become embedded in the small-bowel mucosa. Here they lay embryonated eggs, from which rhabditiform larvae are released. The rhabditiform larvae migrate into the bowel lumen and travel down the intestines, passing out in the feces [4]. However, one important feature of some nematodes, including *Strongyloides* spp., is their ability to cause autoinfection. This means that the parasite never reaches the soil. Instead, the rhabditiform larvae develop into “infectious” filariform larvae in the bowel and directly infect the mucosa of the bowel, specifically the colon (endoautoinfection) and perianal skin area (exoautoinfection) [4]. Depending on its life cycle, different stages of *S. stercoralis* can be found in different parts of gastrointestinal tract [5]. As shown in this case, adult worms and rhabditiform larvae can be found in biopsy specimens of the duodenum and filariform
larvae can be found in biopsy specimens of the colon. Here, we have clearly demonstrated both the different endoscopic features and the different stages of the life cycle of S. stercoralis in a single case.
