A case of delayed bleeding after endoscopic submucosal dissection for completely circumferential esophageal cancer

Endoscopic submucosal dissection (ESD) for early esophageal cancer is being performed more frequently. Perforation and stricture are well-known complications of esophageal ESD, but delayed bleeding is very rare. This is the first report of delayed bleeding after esophageal ESD.

An 82-year-old man was admitted to our hospital to undergo endoscopic ESD for a superficial esophageal cancer 60mm in diameter that involved the entire circumference of the esophageal lumen (Fig. 1). En bloc resection of the tumor was performed successfully without any complications (Fig. 2). To prevent post-ESD stricture, triamcinolone acetonide was injected into the remaining submucosa immediately after ESD.

The following morning, the patient vomited a large volume of blood, and an emergency endoscopy was performed. After numerous clots had been removed with grasping forceps, the bleeding was stopped with hemostatic forceps (Video 1). Fortunately, endoscopic balloon dilation was not required after one local injection and the systemic administration of prednisolone. The patient was able to ingest all foods without any symptoms at 1 year after ESD (Fig. 3).

Bleeding after esophageal ESD is very rare. From March 2007 to March 2015, the rate, including this case, was 0.19% (1/529) in our experience. Tsujii et al. reported no cases of post-ESD bleeding in 368 patients [1]. This absence of post-ESD bleeding is unexplained but may be related to the lower level of exposure to gastric acid after esophageal ESD than after gastric ESD. In this patient, hypertension (systolic blood pressure > 190 mmHg) after ESD may also have played a role.

In patients with post-ESD bleeding, clips are typically effective for hemostasis. However, in circumferential ESD for esophageal cancer, hemostatic forceps should be used because such lesions are associated with a high risk for post-ESD stricture, which may require endoscopic balloon dilation.

Fig. 1 Endoscopic views with iodine staining of a superficial cancer that involves the entire circumference of the esophageal lumen in an 82-year-old man.

Fig. 2 Circumferential endoscopic submucosal dissection is performed without any complications.

Fig. 3 At 1 year after endoscopic submucosal dissection, the ulcer has healed completely without stricture.

Video 1

After the removal of numerous clots with grasping forceps, the bleeding is stopped by soft-mode coagulation with hemostatic forceps.
