Abstract

General thinking has previously centered on managing carotid artery stenosis (CAS) by carotid endarterectomy and subsequently, stenting for higher risk patients. However for CAS and other forms of vascular disease, especially when asymptomatic, there is new emphasis on defining underlying mechanisms. Knowledge of these mechanisms can lead to medical treatments that result in possible atherosclerotic plaque stabilization, and even plaque regression, including in the patient with CAS. For now, the key medication class for a medical approach are the statins. Their use is supported by good cardiovascular clinical trial evidence including some directed carotid artery studies, especially with a demonstrated decrease in carotid intima-media thickness. Procedural controversy still exists but the current era in medicine offers significant support for medical management of asymptomatic CAS while techniques to recognize the vulnerable plaque evolve. If CAS converts to a symptomatic status, early referral for endarterectomy or stenting is indicated.

Basic Definitions and Forms of Vascular Disease

CAS is a component of peripheral vascular disease (PVD) and peripheral arterial disease (PAD). CAS, as a subcategory of PVD, appears to involve a similar atherosclerotic process to that of PAD but the carotid arteries are involved instead. An American Heart Association Symposium in 2008 proposed that PAD should refer specifically to stenosis or occlusion of upper extremity or lower extremity arteries only. Renal, coronary, cerebral, and mesenteric arterial disease as well as all aneurysms are not classified as PAD but are included in the category of PVD.1 Specifically, PAD involves the upper and lower extremities although usually the lower extremities are affected. On the other hand, PVD refers to all cardiovascular disease separate from cerebral arterial disease and coronary heart disease (CHD).2 Confusion exists because PVD and PAD have been used interchangeably and incorrectly in the past. PAD affects approximately 8 million individuals aged ≥ 40 years in the United States.1,3

Vascular disease is an all-encompassing term that refers to the entire range of cardiovascular arterial disease. In the case of PVD as a form of vascular disease, the best data regarding prevalence involve PAD. PAD prevalence increases from a <3% presence at 50 to 59 years of age to >25% of males aged ≥ 80 years.3 The manifestations of PAD are not always clinically overt. Up to 40% of PAD individuals experience no symptoms while awareness of existing PAD is approximately 25%.1,4 Although significantly prevalent, PAD remains underdiagnosed and undertreated because of the absence of symptoms and the lack of overt disease manifestations.3–5
It is relevant to refer to PAD in a review of CAS since the significance of PAD is not only its involvement of the upper and especially lower extremity arteries but the fact that the presence of PAD indicates a high probability of generalized vascular atherosclerosis. This includes a high prevalence of other arterial diseases, namely CHD, CAS, and abdominal aortic aneurysm (AAA). Also, there is a two-way relationship, in that patients with CHD, CAS, and AAA have a high prevalence of PAD.

Over and above the usual stroke and transient ischemic attack (TIA), CAS displays some unique and unusual presentations. A transient postprandial visual loss was reported by Levin and Moota as an occurrence after eating a meal. This occurrence was considered to result from decreased perfusion of the choroidal and retinal circulations in association with severe CAS. Cerebrovascular reserve can be defined as the inverse of the potential for cerebral ischemia in the case of severe CAS. In this case, reduction of cerebral perfusion pressure results in autoregulation of the cerebral vasculature with maximal dilation of cerebral arterioles to maintain cerebral flow. Low cerebrovascular reserve results in increased potential for cerebral ischemia and appears to increase the risk of stroke.

**Diagnosis of Carotid Artery Stenosis**

There have been significant advances in the diagnosis of CAS and if implemented widely, diagnosis can be made early. With a serious effort aimed at altering lifestyle and managing risk, the quality of life of patients can be improved and cerebrovascular complications can be reduced. There are many noninvasive tests available for the diagnosis of CAS which are best performed in a vascular laboratory. Standardization and selection of the best imaging test is a significant problem. In an attempt to address this problem, the Canadian Atherosclerosis Imaging Network was established by the Canadian Institutes of Health Research and the Canada Foundation for Innovation to promote significant clinical research, improve the clinical evaluation of vascular disease associated with cardiac and neurologic vascular problems, improve understanding of underlying disease processes, and improve disease prevention approaches.

**Intra-Arterial Angiography**

The United Kingdom has a program to assess whether imaging modalities, alone or in combination, have the capability to replace intra-arterial (IA) angiography. These imaging modalities include ultrasound (US), magnetic resonance (MR) angiography enhanced with contrast, and computed tomography (CT) angiography. IA angiography has been the gold standard to evaluate CAS. Assessment of the cost effectiveness of less-invasive imaging tests, the effect on stroke/mortality incidence, and the occurrence and cost of carotid endarterectomy is of major clinical significance. This applies especially if improved access to essential endarterectomy for patients at significantly increased surgical risk and for a CAS not accessible to a carotid endarterectomy approach.

**Duplex Ultrasound**

Duplex US scanning of the arterial system can be specifically applied to CAS. This technique is one of the most common noninvasive approaches used by a vascular laboratory to define anatomy, hemodynamics, and lesion morphology. The sensitivity of duplex ultrasonography to detect occlusions and stenoses has been reported to be 95 and 92%, respectively, with specificities of 99 and 97%, respectively. Some limitations with Doppler imaging include evaluation of tandem stenoses. An area of stenosis is localized with color Doppler and assessed by measuring Doppler velocities at several arterial sites. The normal arterial velocity waveform is triphasic. It consists of an initial forward flow systolic peak, then a reversal of flow in early diastole, and finally forward flow in late diastole. With progressive arterial disease, there is elimination of reverse flow, a decrease in systolic peak, and an increase in flow in diastole.

**Computed Tomography Angiography**

IA angiography has been the gold standard for carotid arterial imaging. It is considered to be the only method that defines the anatomy to an extent required by both surgeons and interventionalists. It is considered the optimal method to help choose the best therapeutic option in vascular patients with its utility validated by years of experience. However, with the recent advances in MR angiography and CT angiography in the last decade, valuable results can be achieved in centers with extensive experience in performing and interpreting these studies. Multidetector CT (MDCT) angiography, while requiring the use of contrast and some exposure to radiation, offers some unique advantages over MR angiography. It can be performed in patients with metallic foreign bodies such as metal stents and pacemakers. In addition, there is a relatively simple protocol with shorter time requirements. The technology of MDCT is rapidly evolving and image quality is continually improving. Nevertheless, severely calcified arteries are difficult to evaluate with CT angiography.

**Vascular Assessment with Magnetic Resonance Angiography**

Contrast-enhanced MR angiography using gadolinium as the contrast agent offers excellent images. It was developed to provide another noninvasive alternative to diagnostic CT angiography in the evaluation of vascular disease. In a review and meta-analysis of contrast-enhanced CT angiography, Debray et al in 2008 reported a sensitivity of 94.6% (range, 92.4–96.4%) for detection of severe internal carotid artery stenoses with a specificity of 91.9% (range, 90.3–93.4%). MR angiography is noninvasive other than a simple intravenous gadolinium injection. There is no exposure to harmful ionizing radiation to either the patient or the operator. Also, MR angiography offers great detail of the associated surrounding structures (bone, soft tissue).
addition, MR angiography can contribute stroke-risk information beyond simple stenosis measurement due to its ability to define specific atherosclerotic plaque fibrous cap characteristics such as thinning, rupture, and hemorrhage. MR angiography can also assess the lipid status of any necrotic core and image the entire carotid artery wall, allowing the assessment of aggressive cardiovascular risk management. MR angiography also offers the possible documentation of plaque stabilization and/or regression. However, a limitation of MR angiography imaging is that it cannot be applied in the presence of metal clips or stents since these can cause artifacts that mimic vessel occlusions. In addition, patients with pacemakers, defibrillators, and some cerebral aneurysm clips may not be able to be scanned safely. Also, MR angiography performed with gadolinium has been associated with nephrogenic systemic fibrosis (NSF). This is a rare, but serious, condition that occurs in patients with elevated creatinine levels. The U.S. Food and Drug Administration recently made changes to the drug label for gadolinium-based contrast agents (GBCA) to minimize the risk of NSF associated with the use of GBCA in patients with kidney dysfunction. NSF has not been reported in patients with normal kidney function. Patients at greatest risk for developing NSF after receiving GBCA are those with impaired elimination of the drug, patients with acute kidney injury, and patients with chronic severe kidney disease (with a glomerular filtration rate or GFR < 30 mL/min/1.73 m²). Higher than recommended doses or repeat doses of GBCA also appear to increase the risk for NSF. A meta-analysis of MR angiography compared with catheter angiography demonstrated that the sensitivity and specificity of MR angiography for detection of stenoses greater than 50% were both in the range of 90 to 100%, with greatest accuracy when gadolinium-enhanced MR angiography was used. Most current studies report similar results, with an agreement between MR angiography and catheter angiography of 91 to 97%.

Optical Coherence Tomography
A technique to detect high-risk atherosclerotic plaques in CAS, especially with asymptomatic CAS, is of major interest. Optical coherence tomography (OCT) is invasive as an IA procedure but appears to offer a major possibility to assess potentially vulnerable carotid plaques. This is another imaging modality that is very relevant to assessment of the results of aggressive medical management. An example is the specific capability to evaluate the benefit of statins in patients with CAS.

Basic Concepts of Carotid Artery Stenosis Management
There is a well-established overlap of PVD, PAD, and CHD. In a study of ABI as a correlate of PAD in 273 patients with mean age of 71 years, it was found that of 155 patients with a very low ABI of < 0.40, 130 (84%) had three- or four-vessel CHD. The medical management of PVD, including CAS, centers on decreasing individual cardiovascular risk factors as much as possible.

Stroke is a form of vascular disease, as is atherosclerotic disease of the aorta, carotid arteries, and lower extremity arteries. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial was a randomized, double-blind study designed to determine whether atorvastatin 80 mg/d versus placebo would reduce the risk of fatal or nonfatal stroke. The patients in SPARCL had no known coronary disease and had experienced a stroke or TIA within the previous 6 months. During a median follow-up of approximately 5 years, 11.2% of those receiving atorvastatin and 13.1% of those receiving placebo reached the primary endpoint of fatal or nonfatal stroke. This represented a 5-year absolute reduction in risk of 2.2%; adjusted hazard ratio (HR), 0.84; 95% confidence interval (CI), 0.71–0.99; and p = 0.03. The American Heart Association/American Stroke Association (AHA/ASA) recommendations state that on the basis of the SPARCL trial, administration of statin therapy with intensive lipid-lowering effects is recommended for patients with atherosclerotic ischemic stroke or TIA who do not have known CHD. These recommendations from SPARCL are intended to reduce the risk of stroke and cardiovascular events. Therefore, there is good clinical trial evidence to support intensive cardiovascular risk factor management in the patient with CAS.

Elevation or increased levels of high-density lipoproteins (HDL) are generally considered favorable for cardiovascular risk status. However, even though this is well-established from an epidemiologic standpoint, there is increasing information that not all HDL are good. In a community-based cohort study using MR spectroscopy in 930 participants aged 45 to 70 years, Qi et al found that cholesterol-overloaded HDL particles were independently associated with worsening of carotid atherosclerosis.

Statins in the Medical Management of Carotid Artery Stenosis
Despite the role of statins in favorably modifying cardiovascular risk, the potential value of a healthy lifestyle should never be forgotten. Of relevance are the results from the Prevención con Dieta Mediterránea (PREDIMED) trial which showed that consuming a Mediterranean diet with the addition of nuts (in this case, extra virgin olive oil as a supplement did not make a difference) delayed the increase in carotid intima-media thickness (CIMT) and plaque progression. Similar results were seen with an intensive multiple cardiovascular risk factor intervention in 97 patients with type 2 diabetes mellitus (DM). Over 2 years, an intensive risk factor intervention resulted in a significant decrease in CIMT. There is ample evidence that statins appear to decrease the progression of CIMT, may improve peripheral endothelial function, and offer the possibility of reversing atherosclerosis. The Stop Atherosclerosis in Native Diabetes Study (SANDS) found that in patients with type 2 DM, reducing both low-density lipoprotein cholesterol (LDL-C) to an aggressive target of 70 mg/dL and systolic blood pressure to 115 mm Hg resulted in regression of CIMT and a decrease in left ventricular mass. In SANDS, a statin was
started if lifestyle modification failed to attain the desired LDL goal; if this did not occur with the addition of a statin, ezetimibe was added.

LDL-C is the most specific lipoprotein target associated with CHD, and as such is considered the gold standard of CHD risk factors. LDL-C is the only lipoprotein with strong evidence to support its reduction as beneficial in decreasing acute and chronic cardiovascular events and associated diseases including PAD. Of all the medications available to manage and decrease LDL-C, statins are the cornerstone and the first medication to initiate after restricting cholesterol and saturated fat intake. For the high-risk cardiovascular patient, including any patient with proven CHD, PAD, DM, or saturated fat intake, ezetimibe contributes significantly by contributing up to an additional 24% LDL-C reduction while keeping statins at a safer, lower, long-term dose. This occurs while still preserving the majority of statin LDL-C reduction and beneficial pleiotropic effects.

Despite excellent evidence supporting the beneficial effects of statins in cardiovascular risk management, the specific benefit of statins has been more problematic in the case of PAD and CAS patients, particularly perioperative outcomes. Nevertheless, all vascular patients should be on a statin for secondary cardiovascular disease prevention. In a study of 328 patients with asymptomatic CAS scheduled for elective carotid endarterectomy, Heyer et al reported that preoperative statin use was associated with decreased neurological injury following endarterectomy. Such data, of course, eliminates the possibility of a prospective randomized trial. Furthermore, age is not a qualifying issue and elderly patients with a history of stroke or TIA are benefited by the use of a statin.

Significant but asymptomatic CAS still evokes controversy regarding an invasive endarterectomy or stenting approach, since this is being done in approximately 70% of the asymptomatic cases. Nevertheless, there is increasing evidence to consider asymptomatic CAS a medical condition. Unless microemboli are identified on transcranial Doppler, the 20 year risk of stroke in asymptomatic CAS is 1% or less. Unfortunately, there are surgical and interventional conflicts involved regarding asymptomatic CAS. Billed as a transatlantic debate, Schneider and Naylor recognized the need for an adequately powered trial with treatment arms for endarterectomy, stenting, and best medical therapy. In contrast, Naylor concluded that a very large majority of asymptomatic CAS patients will never develop a stroke, only 1% of strokes will be prevented by a mass campaign of intervention, and 94% of interventions in asymptomatic CAS patients may be unnecessary. It can be effectively argued that only where carotid endarterectomy can be performed with a combined periprocedural stroke and death rate of <3% should endarterectomy be advised for asymptomatic CAS, prompting some physicians to avoid a routine screening policy. Therefore, a specific correct approach to asymptomatic CAS has not been established but nevertheless, conversion to symptomatic status should lead to urgent medical attention. In the future, procedures such as OCT may identify vulnerable carotid plaques that should be urgently managed with an invasive approach.

**Prognosis of Carotid Artery Stenosis**

The purpose of intensive medical management for any vascular disease, including CAS, is in small part to aid symptom relief. Nevertheless, prevention is the major goal with a desired result of improving prognosis. Van Kuijk et al screened 2,933 consecutive patients with symptomatic PAD before surgery for their PAD. The screening was done for associated cerebrovascular disease and CHD, bringing the assessment to a total of three affected vascular beds (AVB). During a median follow-up of 6 years, 1,398 patients died with 54% of the deaths secondary to a cardiovascular etiology.
After adjustment for baseline risk factors and discharge medications, a HR with CI was determined and the presence of two and three AVBs was associated with increased all-cause mortality (HR 1.3, 95% CI 1.2–1.5; HR 1.8, 95% CI 1.5–2.2, respectively) and increased cardiovascular mortality (HR 1.5, 95% CI 1.2–1.7; HR 2.0, 95% CI 1.6–2.5, respectively). The results showed that involvement of multiple vascular beds in PAD patients is a significant and independent risk factor for all-cause and cardiovascular mortality.

On the other hand, Welten et al reported that the long-term prognosis of PVD surgery patients is significantly worse than for CHD patients. They studied 2,730 patients undergoing PVD surgery and placed them into four groups as follows: carotid endarterectomy for CAS (n = 560), elective abdominal aortic aneurysm (AAA) surgery (n = 923), acute AAA surgery (n = 200), and lower limb reconstruction procedures (n = 1,047). The lower limb procedures consisted of iliac–femoral, femoral–popliteal, or femoral–tibial artery bypass; removal of infected prostheses; opening of peripheral obstructions; and other elective peripheral arterial surgical reconstructions. The PVD patients had a poorer long-term prognosis (HR 2.40, 95% CI 2.18–2.65) than CHD patients (p < 0.001). The major cause of death in these PVD patients was cerebrovascular complications (46%). There was no significant difference in long-term survival noted between AAA and lower limb reconstruction groups (log r and p = 0.70).

Conclusions
An aggressive medical cardiovascular risk reduction approach, centered around the use of a statin when CAS is present, is the current standard of care, supported by ample clinical trial evidence. Therefore, it can be unequivocally stated that any patient with CAS should be aggressively managed with a statin to achieve LDL-C reduction to less than 70 mg/dL or an even lower LDL-C level if the initial one was close to 70 mg/dL. This can be recommended despite failure to obtain agreement on the use of endarterectomy, stenting, or medical management only, regardless of whether or not the CAS is asymptomatic or symptomatic.

Conflicts of Interest
The author has no conflict of interest to declare involving any pharmaceutical company, medical device company, stock ownership, or any other possible perceived conflict.
