Abstract

Introduction Otosclerosis is a primary disease of the temporal bone that leads to stapes ankylosis. Hearing loss is the main symptom. Treatment includes surgery, medical treatment, and sound amplification therapy alone or in combination.

Objective To evaluate the functional outcomes of patients with clinical diagnosis of otosclerosis undergoing primary stapes surgery in a teaching institution.

Method Retrospective descriptive study.

Results A total of 210 ears of 163 patients underwent stapes surgery. Of the 163 patients, 116 (71.2%) underwent unilateral surgery and 47 (28.8%) underwent bilateral surgery. Six of the 210 operated ears had obliterative otosclerosis. The average preoperative and postoperative air–bone gap was 32.06 and 4.39 dB, respectively. The mean preoperative and postoperative bone conduction threshold was 23.17 and 19.82 dB, respectively. A total of 184 (87.6%) ears had a residual air–bone gap <10 dB, and 196 (93.3%) had a residual air–bone gap ≤15 dB. Two patients (0.95%) had severe sensorineural hearing loss.

Conclusion Stapes surgery showed excellent functional hearing outcomes in this study. This surgery may be performed in educational institutions with the supervision of experienced surgeons.

Introduction

Otosclerosis, also known as otospongiosis, is a primary disease of the otic capsule that leads to stapes ankylosis.1 Hearing loss is the main symptom. Complaints of continuous tinnitus and eventual vertigo are also observed.1,2 Otosclerosis is considered an autosomal dominant disease.

Genetic investigations in large families with autosomal dominant otosclerosis identified seven loci (OTSC15, OTSC7, OTSC8), although none of the corresponding genes have been found. However, a recent study suggests the implication of the T cell receptor β locus as the causative gene in the OTSC2 region.3,4 Several researchers have come forth with association studies which have revealed the implication of COL1A1,3 TGFβ1, BMP2, BMP4, ACE, AGT, and RELN in the disease development of otosclerosis, although the associations with COL1A1, ACE, and AGT are controversial.5,6 Clinical otosclerosis is present in 0.5% to 1.0% of the population and shows bilateral symptoms in 70% to 85% of
Otosclerosis is more commonly diagnosed in women (female: male ratio of 2:1) and most frequently affects white individuals aged 20 to 40 years; it is less common in Asians and rare in Africans. Recently, according to Ueda et al, there has been an increasing incidence of otosclerosis in Japan, with a proportionate increase in indications for surgical treatment.

Conductive or mixed hearing loss in patients with otosclerosis is determined by involvement of the stapes footplate. However, sensorineural hearing loss eventually occurs, and its cause has not yet been determined. As proposed by Candela et al, the sensorineural component is due to invasion of the spiral ligament by the otosclerosis. In 1919, Wittmaack suggested that sensorineural hearing loss occurs as a consequence of toxic or inflammatory material deposited within the cochlea.

Treatment for otosclerosis includes surgery, medical treatment, and sound amplification therapy, alone or in combination. Otolaryngologists should analyze each patient individually and decide which treatment will provide the best functional outcomes.

Stapes mobilization to treat otosclerosis was initiated in 1952 by Rosen and modified in 1956 by John Shea, who performed the first stapedectomy. Stapes surgery is currently the treatment of choice for conductive hearing loss in patients with otosclerosis. Over time, there have been changes in surgical techniques, types of prostheses, and surgical materials, in an attempt to decrease the risks and complications of surgery and achieve better functional results. Furthermore, recently, the use of the laser technique is increasing gradually with developing technology.

The initial surgery for all patients was stapedotomy; however, 32 patients had a floating footplate or fracture and, thus, underwent conversion to stapedectomy.

Methods

The authors of this study retrospectively reviewed data from 210 ears (163 patients) that underwent operations in the past 5 years by third-year residents under the supervision of the same otology surgeon. All patients with clinical otosclerosis had chosen estapedotomy/estapedectomy as a treatment to improve their hearing loss.

Pure tone audiometry was performed in all patients preoperatively and postoperatively in all frequencies. The bone conduction (BC) and air conduction (AC) were evaluated at the frequencies of 0.5, 1.0, 2.0, and 3.0 KHz, and the preoperative and postoperative residual air-bone gap and its gain were calculated.

The initial surgery for all patients was stapedotomy; however, 32 patients had a floating footplate or fracture and, thus, underwent conversion to stapedectomy.

Surgery

All patients underwent operations using the same technique. The surgery was performed under general anesthesia, and the team used a transtympanic approach with an auricular speculum and holder. First, a tympanomeatal flap was elevated. The chorda tympani nerve was preserved, and the bone wall was cut to expose the oval window. The oval window was inspected to verify the focus of otosclerosis, and the ossicular chain was gently tested to confirm stapes fixation. The tendon of the stapes muscle was cut with Bellucci scissors. The stapes superstructure was disarticulated from the incus and fractured on the promontory. The distance between the footplate and the long process of the incus was measured, and the piston was cut with the addition of 0.25 mm to the measured distance. A third-year resident opened the stapes footplate in the central-posterior portion with a manual punch and the assistant surgeon delicately expanded it with a punch until it was slightly larger than 0.6 mm (0.7–0.8 mm).

A teflon piston 0.6 mm in diameter and 4.25 to 4.50 mm in length was used in all cases. The oval window was naturally sealed with blood clot. The piston was expected to close spontaneously; when this did not occur, it was gently closed with McGee tweezers. The third-year resident placed all prostheses. These maneuvers were performed in the absence of any type of bleeding, especially after perforation of the stapes footplate. Postoperative corticosteroids and cinnarzine were routinely prescribed for 7 and 30 days, respectively.

The patients were hospitalized for two days and returned for follow-ups at 7, 15, and 30 days, postoperatively. Audiometric tests were performed at 45 to 60 days, 6 months, and 1 year, postoperatively.

Results

A total of 210 ears of 163 patients underwent stapes surgery. Of the 163 patients, 116 (71.2%) underwent unilateral surgery and 47 (28.8%) underwent bilateral surgery; 101 (48.1%)
underwent surgery on the right side, and 109 (51.9%) underwent surgery on the left side. The majority of patients were female (64.4%), and the mean age of all patients was 43.56 ± 10.81 years (Table 1).

The average preoperative and postoperative thresholds at the frequencies of 500, 1000, 2000, and 3000 Hz and the average air–bone gap and related gains are presented in Tables 2 and 3.

- Table 2 shows that the average preoperative and postoperative AC was 55.23 and 24.22 dB, respectively. The mean preoperative and postoperative BC was 23.17 and 19.82 dB, respectively. The average preoperative and postoperative air–bone gap was 32.06 and 4.39 dB, respectively. There was statistically significant variation between the preoperative and postoperative times (p < 0.001) in the AC and BC thresholds and air–bone gap. Results show that 91.4% of patients showed improvement in the AC, 64.3% of patients showed improvement in the BC, and 87.6% of patients had a successful surgical outcome, as determined by a postoperative air–bone gap of <10 dB.11 Seventeen (8.1%) ears had a residual gap from 11 to 20 dB, and 9 (4.3%) had a residual gap of >21 dB.

Of the 17 patients with a residual air–bone gap from 11 to 20 dB, four patients had a gap of 11.25 dB, one patient had a gap of 12.00 dB, five had a gap of 12.50 dB, two had a gap of 13.75 dB, three had a gap of 15.00 dB, and two had a gap of 18.75 dB. A total of 196 (93.3%) patients had a residual gap of ≤15 dB. Considering that the average preoperative gap was 32.06 dB, a residual gap of ≤15 dB is an important audiometric gain.

Two patients (0.95%) had severe sensorineural hearing loss. In the first, otorrhea associated with severe vertigo developed in the immediate postoperative period, and the patient was diagnosed with infectious labyrinthitis. The second patient presented with sudden deafness after a hypertensive crisis at three months, postoperatively.

- Table 3 shows that variations in the AC and BC were statistically lower in patients with obliteratorive otosclerosis (p = 0.04 and 0.009, respectively) than in patients without obliteratorive otosclerosis, but the change in the air–bone gap was statistically similar between the two groups (p = 0.447).

### Discussion

In 2006, Vincent et al22 performed a prospective study in which the results of 3050 stapedotomies were analyzed over a period of 14 years. The mean preoperative and postoperative air–bone gap was 25.6 and 1.7 dB, respectively, and the gap was ≤10 dB in 94.2% of cases. In 2013, Oeken23 published a study of 256 cases of stapedotomy in which the postoperative air–bone gap was ≤10 dB in 220 cases (86%). In 2013, Ataide et al24 observed the same result in 75.8% of patients undergoing stapedotomy. Therefore, the audiometric results obtained in the present study are consistent with those in the literature.

The mean preoperative and postoperative BC was 23.17 and 19.82 dB, respectively. Thus, this improvement characterizes the phenomenon described by Carhart.7 The phenomenon is defined as a mechanical process involving the utilization of the energy of the sound wave that enters the external auditory canal and middle ear. This energy is not

used when fixation of the stapes footplate is present, as in patients with otosclerosis.\textsuperscript{7}

Although Fisch’s reverse technique is safer for residents to perform because it avoids dislocation/subluxation of the incus, floating footplate, and even footplate fracture, the surgical field is limited. Moreover, it is contraindicated in patients with otosclerotic otosclerosis, a small or underexpanded oval window by a prominent facial nerve.\textsuperscript{11}

Therefore, appropriate surgical instruments are essential to obtain good stapedotomy/stapedectomy outcomes. Based on the present results, we currently avoid excessive manipulation of the stapes footplate and recommend stopping the surgery after a few attempts to perforate the footplate.

Two patients (0.95%) presented with severe sensorineural hearing loss. The first patient developed sudden deafness three months, postoperatively. The second patient had an infectious labyrinthitis in the immediate postoperative period and audiometry on postoperative day 10 showed deafness in the operated ear.

**Conclusion**

Stapes surgery shows excellent functional hearing outcomes and can be performed in educational institutions under the supervision of experienced surgeons.
