Abstract

Introduction: Prolactin circulates predominantly as a 23 kDa monomer, and a high molecular weight form largely consisting of a complex of prolactin and anti-prolactin IgG autoantibody called macroprolactin. The latter cross-reacts with conventional laboratory assays for prolactin.

We here describe the use of serial macroprolactin measurement to assist in the management of a pregnant lady with pre-conception hyperprolactinaemia in whom a magnetic resonance imaging scan had not been performed.

Case Report: A 24-year old lady was found to have a raised prolactin level of 2 332 µu/L (reference range: 40–530 µu/L). Prolactin was checked because of primary infertility. Macroprolactin screening was positive, accounting for 54% of measured prolactin (estimated monomeric prolactin = 1 073 µu/L).

As expected, measured prolactin levels rose through pregnancy to 6 975 µu/L at 20 weeks and to 8 374 µu/L at 36 weeks gestation.

Adjustment for macroprolactin and big prolactin gave estimated monomeric prolactin levels of 2 370 µu/L at 16 weeks (macroprolactin/big prolactin=66%), 2 441 µu/L at 20 weeks (macroprolactin/big prolactin=65%) and 2 596 µu/L at 36 weeks (macroprolactin/big prolactin=69%). Thus, adjusted prolactin fell within the reference range for pregnancy at these points.

Gel filtration chromatography was performed on the 20-week (second trimester) sample and compared with the pre-pregnancy sample. The pattern remained similar but all components were increased in the second trimester sample (including the monomeric, big prolactin and macroprolactin forms).

Conclusion: In this case report, serial measurement of macroprolactin with estimation of monomeric prolactin enhanced clinical management throughout pregnancy, saving unnecessary further investigations and avoiding unnecessary distress for the patient.

Introduction

Prolactin is an anterior pituitary hormone. It was identified in animals as early as 1933 [1] but only purified in humans in 1972 [2]. In the majority of individuals, prolactin circulates predominantly in the form of a 23 kDa monomer (80% of circulating prolactin; the active form), with trace amounts of a 50–60 kDa dimeric species (‘big’ prolactin; accounts for 10–15%) and a high-molecular-weight (> 150 kDa) complex of monomeric prolactin and commonly an anti-prolactin IgG autoantibody termed ‘big-big’ prolactin or macroprolactin, which can be identified on gel filtration chromatography [3,4]. As a result of its high molecular mass, macroprolactin is confined to the vascular system in vivo and hence is not bioavailable [5]. Delayed metabolic clearance together with detection by many automated prolactin immunoassay systems [6] leads to pseudo-hyperprolactinaemia in patients harboring this form of complexed prolactin.

It was 1974 when Rogol and Rosen [7] reported for the first time that big prolactin may be the predominant form of prolactin in the serum of some patients with hyperprolactinaemia, while in 1981 Whittaker et al. [8] observed that fertility was maintained even when circulating levels of macroprolactin were significantly elevated. The symptoms of hyperprolactinaemia that prompt measurement of prolactin are non-specific and may occur coincidentally in patients who present with hyperprolactinaemia due to macroprolactin [9,10].
Fraser et al. [11] showed that all subjects demonstrated a rise in both monomeric prolactin and macroprolactin during pregnancy, with a consistent tendency for monomeric prolactin to increase to a proportionately greater extent than macroprolactin. The data suggested that plasma concentrations of macroprolactin are much less sensitive to pregnancy than prolactin.

We here describe the use of serial macroprolactin measurement to assist in the management of a pregnant lady with pre-conception hyperprolactinaemia in whom a magnetic resonance imaging (MRI) scan had not been performed.

Case Report

Background

A 24-year-old lady was found to have a raised prolactin level of 2 332 µL (reference range: 40–530 µL). Prolactin was checked because of primary infertility in the context of a normal menstrual cycle of duration 30 days. Thyroid function was normal.

Before MRI imaging of the pituitary gland could be performed, she conceived her first pregnancy. The lady whose case is described was not taking any medication during the period of monitoring reported here.

Laboratory analyses

Routine assays

Serum prolactin levels were measured using a 2-site chemiluminescent immunometric assay on the Siemens Immulite 2500 analyser (Siemens Immulite 2500 analyser; Siemens Healthcare Diagnostics, Frimley, Camberley, Surrey, UK).

Polyethylene glycol precipitation

To estimate the amount of bioactive monomeric prolactin present, specimens were assayed for prolactin after treatment with polyethylene glycol (PEG) 6 000 (25%). PEG precipitation is a method that is simple and inexpensive to perform and is commonly used as a screening test for macroprolactin. Briefly, 300 µL serum, mixed with an equal volume of 25% (weight/vol) PEG 6 000 in phosphate buffered saline (pH 7.4), was incubated for 10 min at room temperature. After clarification of the suspension by centrifugation for 10 min at 3 000 rpm, the monomeric prolactin level in the supernatant was quantified by assay on the Siemens Immulite 2500. The reproducibility of the PEG precipitation procedure was monitored by inclusion of control sera in each assay.

Gel filtration chromatography

Gel filtration chromatography of the serum samples was performed at the Department of Clinical Chemistry, Southend Hospital, Westcliff-on-Sea, UK, as previously described [12]. A 60-cm × 1.6-cm column of Superdex SD-75 with an AKTA protein purification system (Pharmacia 0.5 mL of serum was applied to the column and eluted with Tris-buffered saline, at pH 7.4. Fractions (1.4 mL) were collected and prolactin was measured to the column and eluted with Tris-buffered saline, at pH 7.4.

Fraser et al. [11] showed that all subjects demonstrated a rise in both monomeric prolactin and macroprolactin during pregnancy, with a consistent tendency for monomeric prolactin to increase to a proportionately greater extent than macroprolactin. The data suggested that plasma concentrations of macroprolactin are much less sensitive to pregnancy than prolactin.

The patient remained well throughout the pregnancy. Visual fields were formally assessed serially throughout pregnancy with no abnormality identified. Pregnancy went to term with a healthy baby boy being delivered.

Results

Macroprolactin screening was positive by PEG precipitation at this point, accounting for 54% of measured prolactin (estimated monomeric prolactin = 1 073 µL). During pregnancy, prolactin levels often increase by 10–20 times (reference values for the 2nd trimester = 2 332–6 996 µL). For the third trimester = 2 904–7 886 µL [13, 14]. In this case, as expected, measured prolactin levels rose through pregnancy to 6 971 µL at 16 weeks, 6 975 µL at 20 weeks and to 8 374 µL at 36 weeks gestation.

However, adjustment for macroprolactin and big prolactin gave estimated monomeric prolactin levels of 2 370 µL at 16 weeks (macroprolactin/big prolactin = 66%), 2 441 µL at 20 weeks (macroprolactin/big prolactin = 65%) and 2 596 µL at 36 weeks (macroprolactin/big prolactin = 69%). Thus, adjusted prolactin fell within the reference range for pregnancy at these points [13, 14].

Gel filtration chromatography traces of the 20-week (second trimester) sample compared with the pre-pregnancy sample can be seen in Fig. 1. The pattern of the different serum isoforms of prolactin remained similar for both samples, but all components were increased in the second trimester sample (including the monomeric, big prolactin and macroprolactin forms). Total prolactin was 8 589 µL (41% macroprolactin, 24% big prolactin) and the estimated monomeric prolactin was 3 006 µL, which is within the reference range for this stage of pregnancy.

Clinical course

Our patient remained well throughout the pregnancy. Visual fields were formally assessed serially throughout pregnancy with no abnormality identified. Pregnancy went to term with a healthy baby boy being delivered.

Fig. 1 Gel filtration chromatography of the second trimester sample compared with the pre-pregnancy sample. The pattern is similar but all components are increased in the second trimester sample.
An MRI scan of the pituitary was performed post-partum (Fig. 2). This showed a right sided pituitary adenoma, maximum diameter of 5 mm with evidence of central necrosis/haemorrhage. The total prolactin level continued to fall, with an adjusted level after PEG precipitation of macroprolactin being normal at 388 μU/L 6 months after delivery (reference range: 40–530 μU/L).

Discussion

Serial measurement of macroprolactin, with estimation of monomeric prolactin, enhanced clinical management throughout pregnancy and avoided unnecessary further investigations. Treatment with Bromocriptine was avoided. Just as importantly, the patient was reassured. Estimated macroprolactin proportions differed as would be expected between those derived from PEG precipitation and those derived from gel filtration chromatography. Gel filtration chromatography indicated that the pattern of the different serum isoforms of prolactin remained similar for both samples, but all components were increased in the second trimester sample.

Our findings contrast with those of Larrea et al. [15] who determined the molecular size heterogeneity of immunoreactive prolactin in the serum from 2 ovulatory hyperprolactinemic women who had large amounts of serum macroprolactin. Serum samples were obtained throughout the menstrual cycle and pregnancy. During the menstrual cycle and the early stages of pregnancy, the serum prolactin in subjects initially was mostly macroprolactin but later in gestation the prolactin composition shifted from the high molecular weight variants to monomeric prolactin. The authors suggested that structural changes in prolactin occur during pregnancy which are probably influenced by the hormonal environment. Furthermore, cord blood obtained at time of birth was shown to contain appreciable quantities of macroprolactin.

In a notable case study by Diver et al. [16], in a pregnant lady, monomeric prolactin increased, but macroprolactin remained the major immunoreactive prolactin component in serum during pregnancy. In a separate study, Hattori [17] concluded that macroprolactinemia was frequently present in the pregnant women studied (2.9%) and that different etiologies were involved to form macroprolactin.

As stated in our previous article [18], screening for macroprolactin is a key element of laboratory assessment of hyperprolactinaemia. Laboratory reports should include the adjusted monomeric prolactin level instead of just ‘macroprolactin positive’ to assist clinical decision making and to avoid unnecessary further investigations. This is particularly important in cases such as this one where tracking of macroprolactin and adjusted monomeric prolactin is being carried out.

Pascoe-Lira et al. [19] studied the presence of anti-prolactin antibodies in the sera of 209 healthy women at different stages of pregnancy. PEG precipitation revealed macroprolactinaemia in 8 of 209 women (3.8%) and anti-prolactin antibodies were found in 5 of the 8 women. Thus, there is some evidence that macroprolactinaemia may be more prevalent during pregnancy than in the non-pregnant state.

An important clinical point made here is that we avoided unnecessary MRI scans in this lady’s pregnancy. Failure to appreciate that macroprolactinaemia during pregnancy leads to unusually high levels of prolactin has led to diagnostic confusion in the past. At least one case report has described inappropriate investigation, including 2 MRI scans, in a woman who subsequently was found to have macroprolactinaemia [9].

The data presented here is further evidence to support the reporting of ‘adjusted’ monomeric prolactin to aid decision making in the management of patients with hyperprolactinaemia, with application of gel filtration chromatography where appropriate.

Conclusions

In the case of the pregnant lady reported here, serial measurement of macroprolactin, with estimation of monomeric prolactin, greatly enhanced clinical management throughout pregnancy and saved unnecessary further investigations, avoiding untoward distress for the patient. Screening for macroprolactin is now a key element of laboratory assessment of hyperprolactinaemia. In cases where measured prolactin is significantly raised, determination of macroprolactin status may alter the course of management.
