Abstract

This review article presents several pitfalls and limitations of image interpretation of anatomical risk factors for patellar instability. The most important imaging examinations for the work-up of patients with patellar instability are the true lateral radiograph and transverse computed tomography (CT) or MR images of the knee. Primary anatomical risk factors are an insufficient medial patellofemoral ligament (MPFL), patella alta, trochlear dysplasia, increased distance from the tibial tuberosity to the trochlear groove (TTTG), and torsional limb parameters.

Limitations of the Caton-Deschamps index are related to the clear identification of the patellar and tibial articular margin. Classification of trochlear dysplasia according to the Dejour system on radiographs and MR images revealed a weak reliability. The comparability of TTTG values obtained on CT and MR images at various flexion angles and different varus alignments of the knee is limited. Thus MRI performed with a dedicated knee coil may underestimate the TTTG distance compared with CT images. Increased lateral patellar tilt is a consequence of primary anatomical risk factors rather than an independent anatomical risk factor for patellar instability. The pretest likelihood of a torn MPFL on MR images is very high after an acute episode of lateral patellar dislocation.

Surgical restoration of the patellofemoral joint stability addresses the complex multifactorial biomechanics by a custom-made management such as MPFL reconstruction, sulcus-deepening trochleoplasty, as well as medialization and distalization of the tibial tubercle.

Quantification of anatomical risk factors for patellar instability in each person is important for highly individual treatment.

Lateral dislocations of the patella are frequent injuries in sports-active adolescents and young adults.[1] The patellofemoral joint is stabilized by a complex multifactorial relationship of the osseous joint geometry and the force vectors resulting from the quadriceps muscle and capsuloligamentous stabilizers.[2–4] For appropriate treatment planning, the radiologic work-up after an episode of lateral patellar dislocation should assess both the injuries of the knee and the individual anatomical risk factors for patellar instability.[1,3,5–7]

Dejour et al provided reference values for imaging analysis of four major risk factors for patellar instability: patella alta, trochlear dysplasia, increased tuberosity to the trochlear groove (TTTG) distance, and abnormal lateral tilt of the patella.[3,6,8] Additional anatomical risk factors for patellar instability are an insufficient medial patellofemoral ligament (MPFL), torsional limb malalignment, and genu valgum.[5,9–11] Conventional radiographs, computed tomography (CT), and MRI enable quantification of these predisposing anatomical risk factors for patellar

instability.[3,6,9–12] Surgical restoration of the patellofemoral joint stability addresses the complex multifactorial biomechanics by a tailored treatment such as MPFL reconstruction, release or lengthening of the lateral patellar retinaculum, medialization and distalization of the tibial tubercle, sulcus-deepening trochleoplasty, and rarely femoral derotation osteotomy.[6–8,13,14] This review article presents several pitfalls and limitations in the analysis of anatomical risk factors for patellar instability.

Patellar Height

Patella alta, or high-riding patella, is a major risk factor for recurrent lateral patellar dislocations.[3,8] The trochlear groove is the most important osseous stabilizer of the patellofemoral joint.[1] The patella slips into the trochlear groove at ~ 20 degrees of knee flexion.[1,15] A high-riding patella requires higher flexion angles of the knee to slide into the trochlear groove and covers a higher range of motion without osseous stabilization of the trochlear groove.[1,5] Numerous quantification techniques on radiographs were proposed for the diagnosis of a high-riding patella.[16–21] The four most popular patellar height measurement techniques are the Insall-Salvati, Grelsamer-Meadows, Caton-Deschamps, and Blackburne-Peel indexes.[21] Dejour and Le Coultre stated that any patellar height index can be used; however, the Caton-Deschamps index became the preferred standard for the Lyon school of knee surgery (►Fig. 1).[6,8] A

main advantage of the Caton-Deschamps and Blackburne-Peel ratios is the ability to quantify patellar height changes after osteotomy of the tibial tubercle (►Fig. 1).[6] In addition, the Caton-Deschamps index allows simple and reliable patellar height measurements for various degrees of knee flexion, different physical sizes of the knee, variable skeletal maturation, patellar pole abnormalities, and unequal radiographic magnifications.[6,13,22,23] Limitations of the Caton-Deschamps index are related to the clear identification of the patellar and tibial articular margin as well as its difficult application in osteoarthritic knees.[21] The Caton-Deschamps index is determined by the ratio of the distance between the lowest point of the patellar articular surface and the anterior point of the tibial plateau as well as the patellar articular length (►Fig. 1), whereas values > 1.2 indicates a patella alta and values < 0.6 represent a patella baja.[6,17] However the suggested reference values for patella alta and patella baja vary slightly in the literature.

The Insall-Salvati and Blackburne-Peel indexes on radiographs were compared with the corresponding values on CT and MR images.[24,25] A moderate inter-method reliability of patellar height assessment was found for radiographs and CT images as well as for radiographs and MRI for both indexes.[25] The results show that reference values for patella alta and baja based on radiographs cannot be directly applied on CT and MR images.[3] The authors suggested the addition of 0.09 to 0.13 to the so far established cut-off values derived from conventional radiographs for the diagnosis of patella alta and baja on CT and MRI images.[25]

Trochlear Dysplasia

Trochlear dysplasia is considered a developmental anomaly and is one of the most important risk factors for lateral patellar dislocation.[3,5] A decreased depth, a flat or even a convex trochlear surface characterizes trochlear dysplasia (►Figs. 2–6).[3,8,9] Trochlea dysplasia can be diagnosed and classified according to the four types of David Dejour classification by the so-called crossing sign, a reference line along the anterior cortical border of the distal femur, the supratrochlear spur, and the double-contour sign on true lateral conventional radiographs, axial conventional radiographs,

Fig. 1 (a) Caton-Deschamps index of 1.35 on the radiograph indicates a patella alta. (b) Corresponding Caton-Deschamps index was 1.41 on the sagittal intermediate-weighted MR image. Patellar height ratios on MR and computed tomography images are typically slightly higher than patellar height ratios on conventional radiographs (reference 25). (c, d) The 6-week postoperative follow-up radiographs show typical postoperative findings after sulcus-deepening trochleoplasty (arrow, c), medialization and distalization of the tibial tubercle (c, arrows, d). A clear reduction of the patellar height and Caton-Deschamps index was achieved. Medial patellofemoral ligament reconstruction was also performed on this knee.

Fig. 2 Normal trochlea. (a) The radiopaque line on radiographs (black arrows) representing the sulcus of the femoral trochlea in a normal developed trochlea is located more posteriorly compared with the femoral condyles (white arrows) on true lateral radiographs. (b) The normal trochlear sulcus (white arrow) is concave on transverse cross-sectional images (fat-suppressed intermediate-weighted MR image).
Fig. 3 Trochlear dysplasia type A according to Dejour. (**a**) Delineation of the crossing sign (arrow) on true lateral radiographs and (**b**) a shallow femoral trochlea (arrow) on transverse computed tomography or MR images (fat-suppressed intermediate-weighted MR image) defines trochlear dysplasia type A. Nevertheless, the trochlea should still be concave and symmetrical.[8,9]

Fig. 4 Trochlear dysplasia type B according to Dejour. (**a**) The presence of the crossing sign and a supratrochlear spur on lateral radiographs (arrow) in combination with a (**b**) flat or convex trochlea defines trochlear dysplasia type B (arrow).[8,9]

Fig. 5 Trochlear dysplasia type C according to Dejour. (**a**) Coexistence of the crossing sign (white arrow), the double-contour sign (black arrow), absence of the supratrochlear spur on lateral radiographs, a convex lateral facet, and a hypoplastic medial facet (white arrow, **b**) represent type C dysplasia.[8,9] Black arrow on (**b**) points to an osseous avulsion of the medial patellofemoral ligament.

and midsagittal and transverse CT or MR images, respectively (►**Figs. 2–6**).[3,8,9,26,27]

The radiopaque line on radiographs representing the sulcus of the femoral trochlea in a normal developed trochlea is located more posteriorly compared with the femoral condyles on true lateral radiographs (►**Fig. 2**).[8,9] A crossing sign defines trochlear dysplasia and is present if the line of the trochlear sulcus crosses the anterior outline of the femoral condyles on true lateral radiographs (►**Figs. 3** and **5**).[8,9] The location of these crossing lines represents a flattened trochlea

Fig. 6 Trochlear dysplasia type D according to Dejour. (**a**) The presence of the crossing sign, a supratrochlear spur (white arrow), the double-contour sign (black arrow) on lateral radiographs and a distinct asymmetry of the height of the medial (black arrow on **b**) and lateral trochlear facets, the so-called cliff-like pattern (white arrow on **b**) defines type D dysplasia.[8,9]

and indicates the shallowest part of the trochlear sulcus (►**Figs. 3** and **5**).

Two imaging findings differentiate between trochlear dysplasia Dejour type B, C and D.[8,9] These findings are the supratrochlear spur (also called supratrochlear bump) and the double-contour sign (►**Figs. 1**, **6**).[8,9] The supratrochlear spur sign indicates an osseous prominence of the proximal part of the femoral trochlea, which is present if the height is ≥ 3 mm measured from a reference line along the anterior cortical border of the distal femur on true lateral radiographs.[3] This reference line is usually anterior in relation to the sulcus of the trochlea in normal femoral trochlea ($- 0.8 \pm 2.9$ mm).[3] The double-contour sign on lateral knee radiograph refers to a hypoplastic medial trochlear facet that represents a pronounced asymmetry of the height of the medial and lateral trochlear facets (►**Figs. 5** and **6**).[8,9] The double-contour sign of the hypoplastic medial trochlear facet on lateral knee radiographs is located posteriorly to the radiopaque line of the lateral trochlear facet (►**Figs. 1**, **5**, and **6**).[8,9]

Transverse CT or MR images in patients with trochlear dysplasia demonstrate a flattening or even an absent trochlear sulcus that might be assessed subjectively by the overall impression of the trochlear shape, by an trochlear sulcus angle > 145 degrees, or a trochlear depth ≤ 3 mm on a transverse MR image 3 cm proximal to the femorotibial joint space.[8,9,27] A marked ventral trochlear prominence ≥ 7 mm with a step-like transition zone between the anterior femoral cortex and the most ventral point of the trochlear floor on midsagittal MR images is an accurate criterion for trochlear dysplasia.[27] A specific finding for trochlear dysplasia is a nipplelike anterior prominence at the most anterior and proximal part of the femoral trochlea on midsagittal MR images.[27]

True lateral radiographs revealed a higher diagnostic accuracy and are more reliable for the diagnosis of trochlear dysplasia compared with axial radiographs obtained at 30 degrees of flexion of the knee (►**Figs. 2–7**).[26] True lateral radiographs allow assessment of the whole length of the trochlea. In contrast the evaluation of the trochlea on axial radiographs is limited to the small area viewed tangentially.[26] The diagnostic accuracy of trochlear dysplasia is influenced by the degree of knee flexion. Axial views frequently enable radiologic assessment of the trochlea in its distal part,
Fig. 7 (a–e) Normal trochlea and trochlear dysplasia types A, B, C, and D on axial radiographs. This image series demonstrates the limited value of axial radiographs for the reliable diagnosis and classification of trochlear dysplasia. Thus diagnosis of trochlear dysplasia should be based on true lateral radiographs and transverse computed tomography or MR images. The radiographs are from the same patients as Figs. 2–6.

Fig. 8 Increased femoral antetorsion of 39 degrees (= 43 degrees on [a] minus 4 degrees on [b]) and increased tuberosity to the trochlear groove (TTTG) distance of 22 mm (c, d). Femoral antetorsion and TTTG measurements are obtained in hip and knee extension as described in the text and references 37, 74, and 75. These strictly transverse MR images over the proximal femur and knee are acquired by a fast imaging MR technique (single-shot turbo spin-echo) with the following parameters: femur: 25 sections per slab, 5 mm section thickness, 30% intersection distance factor, 25 s acquisition time, spine matrix coil; knee: 18 sections per slab, 5 mm section thickness, 50% intersection distance factor, 25 s acquisition time, 18-channel body array flex coil.

whereas trochlea dysplasia is always located in the proximal part of the trochlea.[26] Greater flexion angle of the knee on axial views delineate the more distal portion of the trochlea.[9] Thus a maximum knee flexion of 45 degrees was suggested

for axial conventional radiographs.[9] Based on our experience, knee flexion angles ≤ 30 degrees on axial views are difficult to realize due to a superimposition of the knee and feet in lower knee flexion angles.

An appropriate positioning to obtain a true lateral radiographs is crucial for the diagnostic accuracy of trochlear dysplasia.[28] It was shown that a rotation deviation of 5 degrees of the distal femur can already cause false-positive or false-negative diagnosis of trochlear dysplasia in normal shaped and dysplastic femoral trochleae, respectively.[28] Thus superimposition of the femoral condyles posteriorly is a good quality criterion for a true lateral radiograph and seems to be mandatory to diagnose and classify trochlear dysplasia correctly on lateral radiographs.[28]

Dejour's four-type trochlear dysplasia classification revealed a fair intraobserver and interobserver agreement on lateral knee radiographs and transverse MR images.[29] The inter-method agreement for Dejour four-type trochlear dysplasia classification between lateral knee radiographs and transverse MR images was also only fair.[29] It was also shown that lateral radiographs underestimate the degree of trochlear dysplasia according the Dejour classification compared with transverse MR images.[29]

Quantitative parameters such as the depth of the trochlear groove, condyle asymmetry, trochlear facet asymmetry, lateral trochlear inclination, lateralization of the patella, the height of the medial and lateral condyle, and the central trochlear height in relation to the width of the distal femur were evaluated on MR images to discriminate a normal and a dysplastic trochlea.[30] The authors found that these quantitative measurements on MR images are of limited value for the assessment of trochlear dysplasia.[30] In addition, measurements on transverse MR images of the femoral trochlea were not reliable to classify trochlear dysplasia type B, C, and D according to Dejour.[30] The weak reliability in classification of trochlear dysplasia according to Dejour on radiographs and on CT and MR images suggest inconsistent treatment planning and a limited comparability of clinical outcomes in studies addressing trochlear dysplasia.

Tuberosity to the Trochlear Groove Distance

An increased lateralization of the tibial tubercle in relation to the trochlear groove lateralizes the force vector of the extensor mechanism of the knee. Lateralization of the tibial tubercle in relation to the trochlear groove can be quantified as the TTTG distance. The TTTG distance measurements were initially described on plain radiographs; today the TTTG distance is measured on CT and MR images.[3,31,32] It was shown that an increased lateralized TTTG distance is an important risk factor in lateral patellar dislocations, which may be surgically corrected by an osteotomy and subsequent medial transfer of the tibial tubercle (►**Figs. 1** and **8**).[3,5,33–35] Conventional axial radiographs at 30 degrees of knee flexion revealed a large measurement error for the TTTG distance quantification compared with CT images.[36] Thus conventional axial radiographs are not appropriate anymore for TTTG distance measurements.[36] In contrast, cross-sectional modalities, either CT or MRI, are suitable for measurement of the TTTG distance[32]: The following TTTG distance measurement technique is used

at our institution: First, the most distal cross-sectional section with full cartilage coverage of the trochlear groove on transverse MR images or the equivalent level on CT images with continuous delineation of the trochlear cortex is   selected. The cross-sectional image with the patellar tendon proximate to its insertion on the tibial tuberosity serves as the distal reference image. The TTTG is measured as the distance between the center of the patellar tendon at its tibial insertion and a reference line through the deepest point of the trochlear groove rectangular to the tangent along the posterior femoral condyles.[37] TTTG distance measurements on CT and MR images revealed an excellent interobserver, intraobserver, and inter-method reliability.[32,38,39] However, a broad range of TTTG threshold values between 15 and 20 mm or greater were proposed.[3,5,33] This may be explained by some differences of the measurement techniques in the literature.[37] For instance, TTTG values were acquired at various flexion and extension degrees of the knee; however, it was shown that the TTTG distance increases significantly in the end-stage extension of the knee.[37,40,41] The mean TTTG values on MR images were 15.1 ± 3.2 mm at full extension, 10.0 ± 3.5 mm at 15 degrees flexion, and 8.1 ± 3.4 mm at 30 degrees flexion in a well-balanced study cohort of asymptomatic volunteers.[37] Using the MR body coil with the knee fully extended caused significantly higher TTTG values compared with MR examinations with a dedicated knee coil where the knee is slightly flexed.[41] In addition, the dedicated knee coil often causes a slight varus alignment of the lower limb, which also explains in part the lower TTTG distances.[39]

As a consequence, the comparability of reported TTTG distance values obtained on radiographs, CT, and MRI at various flexion angles and varus alignment of the knee is limited.[37,39] In particular, MRI in a dedicated knee coil may underestimate the TTTG distance compared with CT.[42]

Anatomical variances and trochlear dysplasia also plays a crucial role in TTTG measurements: It was hypothesized that the reference point of the trochlear groove in trochlear dysplasia is more inferior lateral in comparison with normal trochlear grooves.[43] As a consequence the TTTG distance is underestimated up to 3 mm in knees with trochlear dysplasia compared with normal knees.[43] Furthermore, a decreasing inter- and intraobserver agreement was found with an increasing severity of trochlear dysplasia.[44]

The center of the patellar tendon at its tibial insertion as a soft tissue landmark is a more constant reference point and provides a higher interobserver and intraobserver agreement for TTTG measurements for surgical planning than its widely used osseous counterpart, the most anterior aspect of the tibial tubercle.[45]

Patellar Tilt

An easy and fast patellar tilt measurement on axial radiographs is the lateral patellofemoral angle, formed by a line between the femoral condyles anteriorly and a line between the margins of the lateral facet of the patella (►**Fig. 9**).[46] The lateral patellofemoral angle was open laterally in 97% and with parallel lines in 3% of 100 normal control patients on axial radiographs with a

Fig. 9 Lateral patellar tilt on a radiograph compared with MRI. Normal patellofemoral angle without pathologic lateral tilt on an axial radiograph at a knee flexion of 40 degrees. Severely increased lateral tilt on the MRI obtained at a slight knee flexion. The lateral patellar tilt is influenced by various flexion angles of the knee)reference 40, 49, and 57). The lateral patellar tilt is currently not considered an independent anatomical risk factor for patellar instability.

knee flexion between 20 and 30 degrees. In contrast, the lateral patellofemoral angle[46] was open medially in 20% and with parallel lines in 80% of patients with recurrent symptomatic patellar subluxations.[46]

On transverse CT images, a reference line through the transverse axis of the patella and a line tangential along the femoral condyles posteriorly determine the lateral patellar tilt angle (►**Fig. 9**).[3,8] The mean lateral patellar tilt angle on transverse CT with the knee in extension without quadriceps contraction was significantly higher in patients with patellar instability (28.8 ± 10.5 degrees) compared with the control group (10 ± 5.8 degrees). Quadriceps contraction increased the lateral patellar tilt by a mean of 6 degrees in patients with patellar instability, whereas the control group demonstrated an increase of 1.5 degrees. The authors suggested a threshold value of 20 degrees for lateral patellar tilt on transverse CT images with the knee in extension without quadriceps contraction. Similar lateral patellar tilt characteristics on transverse CT images with and without quadriceps contraction were noted in further studies.[47,48]

Thus prominent lateral patellar tilt was assessed as a major anatomical risk factor for patellar instability.[3,8,47] Extensor apparatus insufficiency, in particular quadriceps dysplasia and vastus medialis dysplasia, was considered as the etiologic factor of prominent lateral tilt in the past.[3,8,47]

However, the current literature has shown that increased lateral patellar tilt is rather a consequence of an increased TTTG distance, patella alta, trochlear dysplasia, insufficient MPFL, and various flexion angles of the femorotibial compartments than an independent anatomical risk factor for patellar instability.[40,49–57] In addition it was hypothesized[58] that a severe knee effusion could increase or diminish patellar tilt.

Finally, it has to be noted that a meta-analysis revealed insufficient evidence to determine the reliability, validity, sensitivity, or specificity of lateral patellar tilt as a radiologic assessment parameter for patellar instability.[59]

Medial Patellofemoral Ligament

The MPFL is consistently found in anatomical dissection with a mean width of 1.9 cm and a mean length of 5.3 cm.[60] Most of the MPFL fibers originate close to the adductor tubercle of the femur, distal to the attachment of the adductor magnus tendon and proximal to the origin of the medial collateral ligament.[60] The

MPFL attaches at the proximal two thirds of the medial margin of the patella.[60] A broad range in thickness and quality of the MPFL was found.[60] The MPFL has a close anatomical relationship with contributing fibers from and to the posteromedial joint capsule, the medial collateral ligament, the medial patellar retinaculum as well as the quadriceps fibers, in particular the musculus vastus medialis obliquus and the vastus intermedius.[5,60] Thus the femoral origin of the MPFL and the free distal edge of the MPFL frequently cannot be clearly delineated in anatomical dissections.[60,61] In addition, the medial patellar retinaculum and the MPFL blend at their patellar insertion and are often difficult to differentiate from each other on routine MR images.[5]

The MPFL is the main medial passive stabilizer of the patellofemoral joint at full extension of the knee and slight flexion up to 20 degrees.[2,61] A biomechanical study has shown that the required force reduced by $\sim$ 50% to displace the patella laterally in a fully extended knee with a torn MPFL compared with a knee with an intact MPFL.[2] This main patellar-stabilizing function of the MPFL decreased promptly as the knee flexed.[2]

Tears of the MPFL may occur in its midportion, at its femoral or patellar attachment, or as combined MPFL tears with several injured ligamentous parts. There are controversial data about the most frequent location of a tear of the MPFL. Some studies found more MPFL tears at the femoral origin compared with the patellar attachment after lateral patellar dislocation and vice versa.[62–68] It was found that the various MPFL injury patterns are related to trochlear dysplasia, patellar height, and TTTG distance.[64]

It was hypothesized that insufficiency to the MPFL is a precondition for an abnormal lateral patellar movement such as in lateral patellar dislocation.[61] The frequency of a partial or completely torn medial patellofemoral ligaments after acute lateral patellar dislocation varies between 78% and 100%; however, most studies reported an injured MPFL in > 90%.[62–66,68] The very high pretest probability of $\sim$ 90% of a partial or completely torn MPFL in patients with a history, clinical and imaging findings of an previous acute lateral patellar dislocations suggests that the therapeutic concept of the orthopedic surgeon in patellar instability will be rather influenced by the locally preferred standard indication regarding MPFL reconstruction than by the MRI findings of the MPFL.

Torsional Limb Alignment

Thirty patients with a history of recent patellar dislocation demonstrated significant higher mean values compared with asymptomatic volunteers for femoral antetorsion (20.3 $\pm$ 10.4 degrees versus 13.0 $\pm$ 8.4 degrees), knee rotation (9.4 $\pm$ 5.0 degrees versus 5.7° $\pm$ 4.3 degrees) and genu valgum (0.81 $\pm$ 0.75 mm versus $-$ 0.28 $\pm$ 0.87 mm) on MR images.[11] The corresponding tibial torsion values did not differ significantly.[11] In addition, quantitative values for trochlear dysplasia, patellar height, and TTTG distance served for the assessment of standard anatomical risk factors for patellar instability and were compared with the torsional alignment values.[11] These standard anatomical risk factors did not correlate significantly with the

obtained torsional alignment parameters.[11] The authors concluded that torsional malalignment might be a so far underestimated primary risk factor in patellar dislocation.[11]

Gender-Specific Differences

Females, in particular between 10 and 17 years of age, have a higher risk for patellofemoral instability.[69] A 33% higher frequency for acute patellar dislocations was reported in female compared with male adolescents with a three times higher risk for recurrent patellar dislocations.[34,69] The higher frequency for patellofemoral instability in females compared with males diminishes by increasing age; however, a slight female predominance persist in adults with a women-to-men-ratio of 54 to 46% for first-time patellar dislocations.[34,69,70] Balcarek et al[34] analyzed the distribution of no-risk pivoting activities (e.g., swimming, cycling), low-risk pivoting activities (e.g., hiking, jogging, dancing), and high-risk pivoting activities (e.g., football, basketball, soccer) for first-time patellar dislocations and found significant gender differences. The authors reported that low-risk and no-risk pivoting activities were more frequent in females with first-time patellar dislocations, whereas high-risk pivoting activities were more common in males. The authors also found that trochlear dysplasia and the TTTG distance is more pronounced in women who dislocate the patella compared with men.[34] Thus it was concluded that the more excessive trochlear dysplasia and the higher TTTG distance in female patients with patellar instability might contribute to an increased risk of lateral patellar dislocations for females compared with males.[34]

In contrast, the TTTG distance and the patellar height did not differ significantly between males and females in the overall study population of Balcarek et al consisting of 100 patients with lateral patellar instability and 157 patients without patellar instability (p value = 0.94).[34]

Current Therapeutic Concepts at Our Institution

Patellar instability is multifactorial; thus imaging and therapeutic strategies have to address several anatomical variants in patients with lateral dislocations of the patella.[3,7,10,14,71] Conservative and operative treatment strategies for patellar instability are highly individual.[7]

Recurrent symptomatic patellar dislocations are much more frequent in patients with previous multiple patellar instability episodes (49%) compared with first-time patellar dislocation patients (17%).[69] Thus a conservative therapy is usually chosen for first-time patellar dislocation patients at our institution.[7] Conservative treatment includes physiotherapy, bracing, weight reduction, and pain medication.[7,71]

In contrast, recurrent lateral patellar dislocations usually undergo surgical interventions such as MPFL reconstruction, sulcus-deepening trochleoplasty, and distalization and medialization of the tibial tubercle.[7,14] Lateral retinaculum release or lengthening is an uncommon procedure for cases with patellar tilting and the clinically diagnosed severe lateral patellar

compression syndrome.[7,14,72] The indication for femoral derotation osteotomy is reserved for rare occasions.[7,14]

MPFL reconstruction is performed in most of the patients with recurrent patellar dislocations.[7] Distalization of the tibial tubercle is done in patients with prominent patella alta with a Caton-Deschamps index > 1.3 with a goal index close to 1.0. Medialization of the tibial tubercle is indicated for a TTTG distance ≥ 20 mm.[3,7,73] A TTTG distance ~12 mm should be achieved postoperatively.

Trochlear dysplasia severe type B and type D have showed a significantly better subjective outcome compared with type A and mild type B.[14] Thus a stricter indication for trochleoplasty was accepted at our institution than is commonly indicated for type D and severe type B trochlear dysplasia and usually not for type A and mild type B.[14] Type C can be treated by trochleoplasty in cases with relevant dysmorphic changes. Trochleoplasty also lateralizes the sulcus, which indirectly corrects an increased TTTG distance by lowering the lateral vector force of the patellar tendon.[14] Thus additional medialization osteotomy of the tibial tubercle is less frequently indicated in trochleoplasty patients.[14]

Summary

The most important imaging examinations for the work-up of patients with patellar instability are the true lateral radiograph and transverse CT or MR images of the knee. The pretest likelihood of a torn MPFL on MR images is very high after a lateral patellar dislocation. Increased lateral patellar tilt is rather a consequence of primary anatomical risk factors than an independent anatomical risk factor for patellar instability. Radiologic reports should provide details about the individual and independent main anatomical risk factors for patellar instability such as patella alta, trochlear dysplasia, increased TTTG distance, and torsional limb parameters.
