Abstract

Objective The transfemoral approach is a common route for catheterization of the supra-aortic vessels in neuroendovascular therapy. However, in some cases, the patient’s anatomy prevents transfemoral catheterization or distal access to the carotid s. In such cases, direct carotid exposure (DCE) for neuroendovascular approaches may be used to treat cerebrovascular diseases.

Methods We present 11 cases in which we were unable to perform the distal approach and DCE was the preferred neuroendovascular treatment procedure.

Results DCE was performed on 11 patients with cerebral aneurysm (n = 8), carotid cavernous fistula (CCF) (n = 1), malignant brain tumor (n = 1), and carotid angioplasty and stenting (n = 1). Ten patients were female; one was male. Ages ranged from 63 to 87 years (mean: 71.36 years). Coil embolization was performed on patients with cerebral aneurysm and CCF. The patient with a malignant brain tumor underwent polyvinyl alcohol particle embolization. The only complication was a carotid artery dissection that occurred in one patient during stenting.

Conclusion DCE for neuroendovascular approaches can be used as an alternative for patients with tortuous vasculature access in the femoral route. In such patients, a combination of neuroendovascular treatment and surgery in a hybrid operating room with angiography is preferred.

Introduction

Direct carotid access for the cerebral arteries is an old technique that was described by Moniz in 1927.¹ As the development of neuroendovascular treatment approaches proceeded, surgeons began performing direct needle puncture of the common carotid artery (CCA). Vertebral origins and posterior circulation were also evaluated via a subclavian approach.² Transfemoral artery catheterization (TFC) was gradually adopted because it is a less traumatic approach to a site where local pressure can be applied for hemostasis. Moreover, a femoral artery with a larger caliber allows for the introduction of larger sheaths than those in the radial or brachial arteries. Further development of novel devices and techniques during the past 2 decades has allowed to use this access route in most patients.³ However, it is sometimes impossible to use the traditional and more familiar transfemoral route in elderly patients characterized by tortuosity of the proximal vasculature and coexistent vasculopathies. In such cases, the neuroendovascular approach...
can be performed via radial or brachial routes. Similar to the femoral artery, the brachial and radial arteries are superficial vessels, easy to palpate and compress, and they are not in close proximity to important parenchymal organs. Transradial catheterization can easily be performed in such patients and is commonly used by neurointerventionalists, especially in vertebral artery investigations. However, both arteries (especially the radial artery) are smaller, and intra-arterial local injection of vasodilators is required to minimize vasospasms. In addition, there is the possibility of median nerve injury during transbrachial catheterization (TBC) that clinicians should address.4

We present 11 cases in which distal routes could not be used and direct access to the carotid artery was deemed necessary. The CCA was surgically exposed, and catheterization endovascular treatments were performed. Afterward, the CCA was sutured under direct vision.

### Material and Methods

In this study, we investigated 11 patients whose carotid artery was directly accessed during endovascular procedures. Preoperative diagnostic evaluations were performed by contrast-enhanced magnetic resonance imaging/magnetic resonance angiography and computed tomography (CT)/computed tomography angiography (CTA). All procedures involved in the endovascular treatment of an intracranial vascular lesion were performed in this manner in a hybrid operating room (OR) equipped with mobile angiography (GE Healthcare, OEC MD 9800, New York, United States) or in an angiographic room (AR) with fixed angiography (Philips Medical, biplane system, Eindhoven, Netherlands) after complete evaluation of the lesions.

Criteria for the direct carotid exposure (DCE) for the neuroendovascular approaches were as follows:

1. Major vessel tortuosity of the thoracic aorta and/or the supra-aortic vessels and bilateral femoral artery stenosis/occlusion.
2. Inaccessibility of the carotid artery via the radial route so that larger guiding catheters were required for complicated procedures.
3. Medically severely compromised patients who could not tolerate open surgery.

DCE was performed in a hybrid OR or in an angiographic suite under general anesthesia. After general skin drapes, a 4- to 5-cm transverse incision was made along the skin crease of the lower neck. The platysma was cut, and dissection was performed to expose the CCA in the usual manner. Vessel loops were placed on the proximal and distal parts of the exposed CCA, and two 5–0 Prolene anchoring sutures were placed in the central portion. The CCA was punctured with an 18G angiography needle in the area of the anchoring suture, and a 0.035-inch wire was inserted via fluoroscopy. An introducer sheath was advanced into the vessel over the wire, and the contrast was injected through the sheath to confirm the position of the distal end of the sheath and ensure vasospasm or dissection. A silk suture was used to anchor the sheath to the skin edge (Fig. 1F). The sheath was removed after the neuroendovascular therapy (NET) anchoring sutures were tied tightly. An additional stitch was performed for extra security.

### Results

Eleven patients ranging in age from 63 to 87 years (mean: 71.36 years; one male and 10 females) were examined. Eight patients underwent coil embolization of cerebral aneurysms. The aneurysms were located at the anterior communicating artery (ACoA) \(n = 2\), posterior communicating artery (PCoA) \(n = 2\), or middle cerebral artery (MCA) bifurcation \(n = 4\). One patient with a carotid cavernous fistula (CCF) underwent coil embolization with stent placement. One patient had a malignant tumor at the right temporal lobe with partial polyvinyl alcohol (PVA) embolization. One patient had symptomatic carotid artery stenosis (> 80%) and carotid artery stenting (CAS) with carotid angioplasty. The only complication, a carotid artery dissection, was observed in this patient. During the operations, 6F or 7F catheters were used. Table 1 summarizes the main observations.

### Case Illustrations

Case 1 was an 80-year-old woman admitted to the emergency department with stupor consciousness. Brain CT and CTA showed a diffuse subarachnoid hemorrhage on the basal cisterns with a large PCoA aneurysm (Fig. 1A, B). Catheter angiography performed in the AR showed severe atherosclerosis and...
tortuosity from the abdominal aorta to the aortic arch and cervical carotid (►Fig. 1C, D). An aneurysm was located on the internal carotid artery (ICA)-PCoA (14.3 mm/C2 16.1 mm). The patient was transferred to the OR, and coil embolization with DCE was performed. The aneurysm was occluded with a neck remnant without any complications (►Fig. 1E–G).

Case 4 was a 68-year-old woman who was admitted with a severe headache. The CTA showed a saccular aneurysm on the ACoA (►Fig. 2A). The brachiocephalic trunk originated from the proximal aortic arch, and carotid selection failed with all types of angiographic catheters on catheter angiography (►Fig. 2B). DCE resulted in complete occlusion of the ACoA aneurysm with coils performed in the AR with three-dimensional rotational angiography (►Fig. 2C–E).

Case 11 was a 67-year-old woman who was incidentally diagnosed with a large right MCA aneurysm on the CTA (►Fig. 3A). The patient had liver cirrhosis, diabetes mellitus, chronic renal disease, and coronary heart disease. Angiography showed severe atherosclerosis on the thoracic aorta and aortic arch (►Fig. 3B). Carotid selection failed, and the angiogram had to be taken from the contrast injection at the orifice of the innominate artery. The detailed geometry of the aneurysm could not be inferred. According to laboratory findings, the patient had moderate kidney dysfunction (blood urine nitrate 27–30 mg/dL, creatinine 1.5–1.7 mg/dL) and a coagulation abnormality due to liver cirrhosis. Physicians recommended the less invasive surgical procedure with restricted use of contrast and careful perioperative care. DCE was performed. The carotid angiogram showed a 12.1 × 11.6-mm MCA aneurysm with a broad neck (►Fig. 3C, D). Coil embolization with two microcatheters was performed, and partial occlusion of the aneurysm with preservation of distal arteries was successfully completed with a decreased amount of contrast and reduced operative time (►Fig. 3E). The patient tolerated the operation and recovered well.

Discussion

Although direct carotid artery access has been used for several years as a common route for cerebral angiography, since the development of newer, more advanced techniques, it has been used only when alternative access is not possible. TODAY, the primary percutaneous access route for selective catheterization of the carotid arteries is the transfemoral approach. Other alternative vascular access routes include the radial and brachial arteries and percutaneous transcarotid CCA access. However, these routes can be impossible in cases of elongation of the aortic arch, the brachiocephalic trunk, or the carotid artery. Vessel tortuosity and stiffness may limit cranial access and cause a 4 to 6% failure rate in such procedures. In addition to anatomical features, other factors, including morbid obesity, severe peripheral atherosclerosis, severe vasculopathies, previous aortic bypass graft surgery, and aortoiliac occlusion, may increase the risk of TFC in ~2 to 10% of patients. In such cases, alternative routes should be considered.

Radial and brachial artery routes may also cause difficulties in a tortuous supra-aortic trunk anatomy. Although it is easier to pass through the right carotid and vertebral arteries, the small caliber of the radial artery increases the risk of arterial injury and postoperative arterial occlusion. In TBC, median nerve injury can be seen following the procedure. One alternative route is percutaneous CCA access. Difficulties in performing this route include the entry angle of the introducer sheath and difficult access-site management following sheath removal in large guiding catheters, especially in patients taking both antiplatelet and anticoagulant medications. Manual compression or novel closure devices are needed after the procedure.
procedure. Additionally the puncture is more distally located and a larger size catheter is usually needed. The main complications seen with this approach include artery dissection and hematomas of the neck that may compromise the airway after the completion of the surgery.

Although DCE for the neuroendovascular approaches is more invasive, it provides safe access because the surgical closure is more efficient than closure devices or manual compression. It has also been reported that percutaneous hemostatic devices may cause complications such as hematoma, thrombosis, pseudoaneurysm, infection, and arteriovenous fistula. In a recent study, it was determined that bleeding at the puncture site may be a serious problem in cases with extensive perioperative anticoagulation, and it can be controlled more effectively through an open surgical approach than by percutaneous maneuvers. Therefore, DCE is likely easier, especially for neurosurgeons. DCE can reduce catheter setup time on target ICA and allows easier handling of microdevices and the use of short and soft guidewires because extra stiffness is not necessary. DCE also offers the advantage of easier and faster catheter exchanges. Therefore, the thromboembolic risk is lower in DCE, which is a familiar procedure for neurosurgeons.

DCE is also recommended in cases of known vascular fragility, such as Marfan disease or Ehlers-Danlos syndrome. In such patients, puncture and repair of the vessel under direct vision is strongly recommended to avoid massive neck hematomas. However, it is important to remember that this surgical procedure may cause cervical hematoma, one of the most frequent local complications. Great care should be taken to avoid bleeding from a back wall puncture. The puncture may be performed with a narrow angle between the catheter course and the artery to reduce the risk of intimal dissection.

DCE can also be performed to treat carotid artery diseases. It was previously demonstrated that CAS with a transcervical approach could be safely performed with good clinical outcomes. In patients at high risk for endarterectomy, retrograde CCA stenting was performed via DCE, and the risk of distal embolization was overcome by clamping the CCA just above the puncture site and aspirating the introducer sheath prior to its removal. This allowed carotid flow reversal and emboli protection without introducing neuroprotective devices. The significant athero-occlusive disease of the CCA at the level of cannulation can lead to dissection of the carotid artery. One patient with severe symptomatic ICA stenosis (>80%) underwent CAS via DCE. The only complication among all 11 patients was observed in this patient: ICA dissection. After ICA angioplasty, the patient recovered well without any deficits.

In contrast, patients who underwent coil embolization of a cerebral aneurysm, PVA embolization of a malignant brain tumor, and coil embolization with stent replacement in CCF were successfully treated without any complications. None of the patients had neck hematomas, bleeding, thrombosis, or emboli. We believe that intracranial endovascular treatments can be performed more safely than those used to treat extracranial carotid artery diseases. Therefore, in ICA stenosis, the risk of dissection can be determined by evaluating the noninvasive vascular imaging during the preprocedural planning stage. We also believe that combined surgery is more comfortable when a hybrid OR with angiography has been set up, and DCE for neuroendovascular treatment can be safely performed, even in complicated patients with tortuous vascular anatomy.

Conclusion

There is an urgent need to consider the use of alternative access routes in addition to the transfemoral approach when performing NET, especially in elderly patients. We believe that DCE for neuroendovascular approaches can be used as an alternative in cases with TFC difficulty due to tortuosity and stiffness of the vessels limiting cranial access. Surgical exposure of the cervical carotid artery allows for direct vision of the pathologic vessel and closure through a purse-string suture, which are important advantages when compared with percutaneous CCA puncture.
