Venous thromboembolism is a significant cause of morbidity and mortality among surgical patients.¹ Administration of a once daily or twice daily dose of enoxaparin during the perioperative period is an accepted method to prevent this life- or limb-threatening complication.^{2,3} However, recent studies examining multiple surgical populations have shown that a standard, “one size fits all” dose of enoxaparin does not produce sufficient levels of anticoagulation to prevent deep vein thromboembolism or pulmonary embolism in many patients.^{4–7} Studies in burn patients have shown that the total body surface area (TBSA) burned is associated with rapidity of enoxaparin metabolism; patients with larger TBSA required higher doses of enoxaparin.^{4,6} This is because extensive cutaneous injury produces a systemic inflammatory effect that increases drug metabolism.⁴ Prior work in plastic and reconstructive surgery patients has shown that increased total body surface area surgically injured (TBSI), quantified with a Lund–Brower Chart, is associated with lower anti-factor Xa levels (aFXa); aFXa is a marker of enoxaparin activity and quantifies extent of anticoagulation. However, comparisons between patients have many confounders. The following case series examines the effect of TBSI on enoxaparin metabolism, using free flap patients as their controls. Lower extremity trauma patients who require initial debridement and later free flap surgeries can demonstrate how an increased TBSI may impact enoxaparin metabolism.

Case 1

A 53-year-old male marathoner and cyclist with a body mass index of 20.9 kg/m² presented with an extensive full-thickness wound over the lateral lower leg and ankle (►Fig. 1A).

He underwent surgical debridement creating a 2% TBSI wound (►Fig. 1B). The patient was started on enoxaparin 40 mg once daily on postoperative day zero. He was enrolled in the University of Utah’s clinical trial examining enoxaparin metabolism using aFXa levels (clinicaltrials.gov NCT02411292). aFXa levels were drawn as per the study protocol, and steady state peak aFXa was 0.41 IU/mL. This value was within the appropriate range of 0.3 to 0.5 IU/mL; patients in this range are considered to have blood thin enough to minimize the risk of venous thromboembolism (VTE).^{5,7–9} Based on our established dose-adjustment algorithm for patients who receive once daily enoxaparin,⁵ no dose adjustment was made.

On postoperative day 4, the patient returned to the operating room for debridement and wound coverage using a left parascapular flap— Anastomoses were performed end-to-side to the anterior tibial artery and end-to-end with two antegrade anterior tibial venae comitantes (►Fig. 1C). During this operation, the patient’s TBSI increased to 6%. After surgery, the patient again received 40 mg of enoxaparin daily per the study protocol. Steady-state peak aFXa was 0.21 IU/mL, and this level was below the appropriate VTE prophylaxis target level of 0.3 to 0.5 IU/mL. The enoxaparin dose was increased to 50 mg once daily and repeat steady state peak aFXa was 0.44 IU/mL. He was discharged on postoperative day 7. The patient had no thromboembolic or bleeding events at 90 days and was back to cycling training at 6 months (►Fig. 1D).

Case 2

A 54-year-old woman with a body mass index of 17.8 kg/m² was referred for orthoplastic management of a Gustillo

3B fracture with exposed hardware. Upon transfer to the University of Utah, she had a large wound with exposed, denuded tibia, exposed fracture line, and exposed hardware (►**Fig. 2A**). She initially underwent surgical debridement,

and a TBSI of 2% was created (►**Fig. 2B**). The patient was started on enoxaparin at 40 mg once daily on post-operative day 0. Steady-state peak aFXa level was 0.55 IU/mL. The peak aFXa level demonstrated therapeutic levels

(aFXa > 0.5 IU/mL) of anticoagulation, and her dose was decreased to 30 mg daily. On postoperative day 4, a two perforator anterolateral thigh flap was used to provide wound closure with an end-to-end anastomoses to the anterior tibial artery and two anterior tibial venae comitantes (►Fig. 2C). This surgery increased the TBSI to 5%. The patient was again placed on enoxaparin 40 mg daily, and steady state peak aFXa level was in range at 0.45 IU/mL. The patient had no thromboembolic or bleeding events at 90 days. She was discharged on postoperative day 7 and had no issues at 1-year follow-up (►Fig. 2D).

Discussion

Patients in this series are in the unique position of being able to act as their control to compare enoxaparin metabolism in response to surgical procedures of different magnitude. In these patients, increased extent of the surgical injury and downstream inflammation was the only major change that may have altered their physiology within the 7-day study period. Previous studies have examined the impact of gross weight and renal function as factors that can affect enoxaparin metabolism.^{2,6} While TBSI has been associated with aFXa levels in the past,⁵ the between-patient comparisons currently available are vulnerable to confounding. The inpatient comparisons made in this study suggest that increased TBSI may make enoxaparin metabolism more rapid, and further suggests that real-time aFXa monitoring and dose adjustment may minimize VTE risk in free flap patients.

In agreement with previous studies, this idea supports the idea that a “one size fits all” enoxaparin dosing regimen may not be ideal for individual patients and demonstrates the utility of real-time aFXa level monitoring and dose adjustment.⁵ This study also highlights the importance of reassessment of VTE risk during hospitalization. Additional risk factors may be acquired during hospitalization, and the effectiveness of prophylaxis strategies may change based on patient-level factors.¹⁰ This case series cannot definitively explain the mechanism behind these changes. However, it is worth noting that patients with larger thermal injuries develop hyperdynamic changes at 48 hours after injury (which corresponds to the time when peak aFXa levels are

drawn) that may increase drug metabolism and drug clearance. While similar changes may be occurring amongst free flap reconstruction patients, further research is needed to identify the mechanism behind observed alterations in enoxaparin metabolism.
