Abstract

In this prospective observational study, we explored the association of daily fluid intake from medication use with fluid overload in 75 children beginning 24 hours after intubation. The mean percent daily fluid intake from medications was 29% in the overall cohort. Excess intake and inadequate output contributed significantly to fluid overload. In the 28 patients who became ≥10% fluid overloaded, the mean percent daily fluid intake from medications was 34%, but just 23% in the patients who did not. Awareness of volume contribution and maximized concentration of parenteral medications when able may lessen the burden of fluid overload.

Keywords

► fluid overload
► fluid management
► medication administration

Introduction

In hemodynamically unstable patients, early and aggressive fluid management is lifesaving.1–3 However, after hemodynamic stability has been achieved, many adult and pediatric investigations have shown a significant relationship between positive fluid balance and mortality in critically ill patients.4–14 Most authors exploring the effects of fluid overload in children in the intensive care unit (ICU) report a worsening of morbidity and mortality when fluid overload exceeds 10 to 20% prior to the initiation of continuous renal replacement therapy (RRT).5–9

There are numerous factors, including an increased risk for acute kidney injury (AKI), impaired water diuresis, and high volumes of fluid input that put pediatric ICU patients at a particularly high risk for fluid overload.15–17 Intravenous (IV) fluids frequently make up a large proportion of an ICU patient’s daily fluid intake.18 The method most commonly cited for calculating maintenance IV fluid rates in children is extrapolated from the method proposed by Holliday and Segar in the 1950s for calculating the caloric needs in the average hospitalized patient.19 By relating caloric expenditure to water loss, and therefore fluid needs, the 100/50/20 or 4/2/1 formula is routinely used today. These formulas are not based on the estimated energy requirements of children in the ICU and can significantly overestimate the fluid needs of critically ill children. Importantly, more recent literature suggests that in an effort to prevent hyponatremia, the volume of IV maintenance fluids obtained with the standard formula proposed by Holliday and Segar should be reduced.20,21

Prior studies have investigated the role of continuous RRT in the prevention and treatment of fluid overload.3–10,22,23 However, little attention has been given to the contribution of fluid intake in the form of medication administration in the development of fluid overload. Daily scrutiny of fluid volume related to medication intake as well as use of maximally concentrated parenteral medications may serve as to lessen the burden of fluid overload. Therefore, we sought to explore the association of fluid intake from medication administration with fluid overload in a cohort of mechanically ventilated children after the completion of acute resuscitation efforts.

Materials and Methods

Study Design

We prospectively obtained fluid intake and output data on all intubated and mechanically ventilated patients during a
A total of 75 patients were included in the analysis. The median age was 8 years with a median serum creatinine of 0.40 mg/dL (Table 1). The median body mass index (BMI) and BMI percentile were 18.8 kg/m² and 85.0, respectively. Seizures and pneumonia were the two most common reasons for admission. Patients were followed up for a mean number of 6.9 days. Fluid overload ≥10% occurred in 28 (37%) of the patients observed using the fluid overload percent equation to calculate fluid overload and in 24 (32%) of the patients using the weight-based formula. In the overall patient cohort, 29% of the mean daily fluid intake was attributed to medication intake. The mean daily percent fluid intake from medications alone was no less than 19% for all age groups with a range of 19 to 39% (Table 2). The proportion of patients with a mean fluid intake that exceeded the definition for polyuria was the largest in the youngest patients with 84% of patients in the 1-month to 2-year-old age group having a mean daily fluid intake that was greater than their threshold for polyuria.

was lower in the patients whose fluid status did not reach 10%, this difference was not statistically significant \((p = 0.30)\). Too much fluid intake and not enough fluid output contributed significantly to whether or not patients experienced \(\geq 10\%\) fluid overload. For example, when comparing the <10% fluid overload group to the \(\geq 10\%\) fluid overload group in patients 1 month to 2 years of age, both the daily mean total fluid intake \((p < 0.001)\) and output \((p < 0.001)\) were significantly lower in the \(\geq 10\%\) group, suggesting that less output was contributing to the development of fluid overload in this patient group. This also occurred when comparing the fluid overload status of children in the 11- to 14-year-old age group \((\text{total fluid intake})\) \((p = 0.001)\); total fluid output \((p = 0.02)\). In contrast, in the 7- to 10-year-old age group, both the mean fluid intake \((p < 0.001)\) and output \((p < 0.001)\) were significantly greater in the \(\geq 10\%\) fluid overload group, suggesting that more intake (rather than less output) was contributing to fluid overload in these patients. It was in this age group \((p < 0.001)\) and the 15- to 18-year-old age group \((p = 0.04)\) that the mean proportion of fluid intake from medications was significantly greater in the \(\geq 10\%\) fluid overload group.

The overall incidence of AKI in the study cohort was 18.7%. The AKI incidence was the highest in the 11- to 14-year-old age group \((55.6\%); \rightarrow \text{Table 3}) The incidence of AKI in patients who were \(\geq 10\%\) fluid overloaded was 17.9% and it was 19.1% in those who were <10% fluid overloaded. This difference was not statistically significant \((p = 0.89)\).

Of the 75 patients observed, 47.3% of patients received a diuretic. Of the 28 patients who were \(\geq 10\%\) fluid overloaded, 20 patients \((71\%)\) were given a diuretic at some point during the observation period. For seven patients who became \(\geq 20\%\) fluid overloaded, five of these patients did not receive a diuretic during the observation period. Only two patients who received a diuretic became \(\geq 20\%\) fluid overloaded.

Discussion

Fluid overload ≥10% was common among our cohort of patients, occurring in 37% of mechanically ventilated patients over a 30-day observation period based on percent fluid balance. We obtained a similar proportion of fluid overload (32%) using a weight-based formula, which is consistent with prior investigations that have compared percent fluid balance to weight-based formulas for calculating fluid overload.9 There was no significant difference in AKI incidence when comparing patients who became ≥10% fluid overloaded to those who did not. Therefore, it does not appear in our overall study cohort that fluid overload represented a reduced renal function as a result of AKI. Interestingly, the two patient groups (1 month to 2 years and 11–14 years) who had the highest incidence of AKI (–Table 3) also had a decreased fluid output which appeared to contribute to the development of fluid overload (–Table 2).

Both too much fluid intake, with medications potentially playing a role, and inadequate fluid output appeared to contribute markedly to the fluid overload. The proportion of fluid intake with medications was greater in the group that became ≥10% fluid overloaded. Given the known negative consequences of fluid overload shown in previous studies, it is important to consider potential changes in practice for the prevention of excess fluid accumulation in critically ill children. Notably, given the results of this analysis, an increased attention to the volume of fluids given with medications is important in the prevention of fluid overload in critically ill children after the acute phase of illness. The Food and Drug Administration, through the Safe Use Initiative, has been working in conjunction with pharmacy and safety organizations including the American Society of Health-Systems Pharmacists, the Pediatric Pharmacy Association, the Institute for Safe Medication Practices, and the Association for the Advancement of Medical Instrumentation to encourage the development of standardized concentrations and dosing units for continuous infusions.28 While the guiding principles of this project include a recommendation to limit to one standard concentration for infusions when possible, it is stated that there is an understanding that two or three concentrations might be necessary especially when considering fluid status and individual patient needs. In the ICU, a physician may not perceive the large proportion of IV fluid intake that is being given with medications, an important modifiable risk factor in avoiding fluid overload.

Our youngest patient group (1 month to 2 years) had the highest proportion of patients with a mean fluid intake who exceeded their definition of polyuria and also the highest proportion of patients who became fluid overloaded. This patient group may represent a particularly vulnerable population for the development of fluid overload and would benefit from the careful attention to fluid intake. In a multicenter study done by the RRT investigators, it was demonstrated that IV fluids make up 86% and enteral nutrition makes up less than 10% of daily fluid intake on day 3 of a pediatric ICU stay.18 Given that humidification during spon-
from medications in those who were or were not fluid over-
loaded. No patients died during our study period; however, we
did not specifically investigate outcomes associated with fluid
overload, although this has been explored in other investiga-
tions.5–9 We calculated the fluid balance beginning 24 hours
after intubation using the standard formula (including admis-
sion weight) to specifically examine the contribution of fluid
intake from medications after the acute resuscitation period.
This may have led to an overestimation of fluid overload, given
that the admission weight was obtained presumably before or
during the acute resuscitation period. It is also possible that
some patients continued to require resuscitation after this 24-
hour period.

In conclusion, it may be prudent for institutions to develop
a drug library subset containing maximum concentrations
reserved for those patients who are or are likely to become
fluid overloaded and require restriction of fluid intake. Anti-
microbial agents, electrolyte boluses, and other medications
diluted in the minimal amount of fluid that can be adminis-
tered safely should be included. The appropriate use of
protocols for maximally concentrated medications when
able is an important factor in avoiding fluid overload. We
should be devoting the same attention to fluid balance when
patients become hemodynamically stable as we do to fluid
administration during the acute phase of illness. Patients
should not automatically be placed on IV fluids according to
weight-based estimates. As a result of the negative sequela
of fluid overload, percent fluid overload should be tracked
daily during admission. The volume of fluids given in medica-
tions should be included in the daily assessment of fluid
status, given that this can account for a significant proportion
of fluid intake. Efforts should be made whenever possible to
utilize the maximal concentrations of parenteral medications
in patients receiving daily volumes greater than their polyuria
threshold. Given the high fluid demands of the pediatric ICU,
the initiation of diuretic therapy or RRT should be discussed
frequently as fluid status is followed closely.
