Hip Flexion Weakness following Transpsoas Interbody Fusion

Fraqueza de flexão do quadril após fusão lombar por via transpsoas

Abstract

Objective  The present work evaluated the motor deficit resulting from the psoas muscle access through the extreme lateral interbody fusion (XLIF) approach.

Methods  This was a prospective, non-randomized, controlled, single-center study with 60 patients, with a mean age of 61.8 years old. All of the subjects underwent a lateral transpsoas retroperitoneal approach for lumbar interbody fusion with electromyographic guidance and accessing 1 to 3 lumbar levels (mean level, 1.4; 63% cases in only 1 level; 68% cases included L4-L5). The isometric hip flexion strength in the sitting position was determined bilaterally with a handheld dynamometer (Lafayette Instrument, Lafayette, IN, USA). The mean value of three peak force measurements (N) was calculated. Standardized isometric strength tests were performed before the procedure and at 10 days, 6 weeks, 3 months and 6 months postsurgery.

Results  Ipsilateral hip flexion was diminished ($p < 0.001$) at the early postoperative period, but reached preoperative values at 6 weeks ($p > 0.12$). The mean hip flexion measures before the procedure and at 10 days, 6 weeks, 3 months and 6 months after surgery were the following, respectively: 13 N; 9.7 N; 13.7 N; 14.4 N; and 16 N (ipsilateral); 13.3 N; 13.4 N; 15.3 N; 15.9 N; and 16.1 N (contralateral). Neither the level nor the number of treated levels had a clear association with thigh symptoms, but hip flexion weakness was the most common symptom.

Conclusions  Patients in the early postoperative period of transpsoas access presented hip flexion weakness. However, this weakness was transient, and electromyography use is still imperative in transpsoas access. In addition, patients must be thoroughly educated about hip flexion weakness to prevent falls in the immediate postoperative period.

Resumo

Objetivo  Avaliar o déficit motor decorrente do acesso através do músculo psoas na técnica de fusão intersomática por via extrevo-lateral (XLIF, na sigla em inglês).

Métodos  Estudo prospectivo, não randomizado, controlado, único centro. Total de 60 pacientes com média de 61,8 anos. Todos os participantes passaram por fusão intersomática lombar por acesso lateral retroperitoneal com monitoração eletroneuromiográfica. Foram operados de 1 a 3 níveis nesses casos (média de 1,4; 63%...
eram de apenas um nível; 68% incluíram L4-L5). A força de flexão isométrica do quadril em posição sentada foi determinada bilateralmente com um dinamômetro de mão (Lafayette Instrument, Lafayette, IN, USA). As médias das medidas de 3 picos de força (N) foram calculadas. Testes isométricos padronizados foram realizados antes e em 10 dias, 6 semanas, 3 e 6 meses após a cirurgia.

**Results** A força de flexão do quadril no lado ipsilateral diminuiu ($p < 0.001$) no pós-operatório imediato, mas em 6 semanas atingiu os valores pré-operatórios. As médias de pré-operatório e 10 dias, 6 semanas, 3 meses e 6 meses após a cirurgia para flexão de quadril medidas foram, respectivamente: (ipsilateral) 13 N; 9,7 N; 13,7 N; 14,4 N; 16 N; (contralateral) 13,3 N; 13,4 N; 15,3 N; 15,9 N; 16,1 N. Nem o nível nem o número de níveis tratados tiveram clara associação com sintomas na coxa, mas a fraqueza de flexão de quadril foi o sintoma mais encontrado.

**Conclusions** O pós-operatório imediato do acesso transpsoas apresentou fraqueza de flexão de quadril após a cirurgia. Entretanto, essa ocorrência é transiente, e o uso da eletroneuromiografia é essencial no acesso transpsoas. Somado a isso, a educação do paciente deve ser amplamente aplicada para alertar sobre a possibilidade de fraqueza de flexão de quadril com o intuito de prevenir quedas no período pós-operatório imediato.

**Materials and Methods**

This was a prospective, single-center, non-randomized study. The present study was approved by the Research Ethics Committee of the Hospital Nove de Julho, São Paulo, SP (66616317.0.0000.5455). A total of 60 patients (39 females), with a mean age of 61.8 years old, were submitted to the XLIF technique by the same spinal team. The inclusion criteria were: patients with degenerative lumbar spine submitted to interbody fusion by the XLIF surgical technique after conservative treatment failure for at least 6 months. One to 3 lumbar levels were instrumented (mean level, 1.37; 63% cases in only 1 level; 68% cases involving L4-L5). Surgeries were performed with retroperitoneal lateral access via the transpsoas approach by senior spinal surgeons.4

The hip flexion strength was evaluated in the sitting position with a handheld dynamometer (Lafayette Instrument, Lafayette, IN, USA). Three measurements of peak force (N) were performed, and the means were calculated. These measurements were assessed in pre- and postoperative evaluations at 10 days, 6 weeks, 3 and 6 months postsurgery, both ipsilateral and contralateral to the surgical access. The strength in both sides was compared. Pain on both sides was also assessed using the visual analogue scale (VAS) questionnaire.5

Descriptive and comparative statistical analyses were performed with the SPSS software (IBM SPSS, Armonk, NY, USA). The comparative statistical analyses between groups were performed using the student t-test and an α value of 0.05.

**Results**

Lateral interbody fusions were performed in 60 patients. The mean age was 61.8 years old (ranging from 22 to 85 years old), and 39 patients were female. Among the 60 cases included in the present study, 38 were single-level arthrodies, and 41 involved the L4-L5 level (Table 1).

A significant 25.4% reduction in the strength of the psoas at the instrumented side was observed between the preoperative measures and those obtained at the 10th day visit (13 N and 9.7 N, respectively) (Fig. 1). Despite this decrease at the 1st postoperative follow-up, the force level returned to baseline 6 weeks after the surgery, and it was sustained until the 3rd month. At the end of the study, the hip flexion strength was higher than before the surgery (16 N).

The reduction of the ipsilateral psoas strength at the 1st postoperative follow-up was not observed on the contralateral side (13.3 N and 13.4 N, respectively). The strength remained constant until the 10th day visit, followed by a
20% increase in subsequent visits, reaching 16.1 N 6 months postsurgery.

No differences were observed between the strength of the ipsilateral and of the contralateral sides before the surgery \((p = 0.71)\). However, a 38% increase in the hip flexion strength was observed on the contralateral side (13.4 N) compared with the ipsilateral side (9.7 N) 10 days postsurgery, a difference that ceased to exist after the 6-week evaluation until the end of the study, at the 6-month visit \((p > 0.05)\).

Regarding the pain in the ipsilateral and contralateral sides, it was observed that, even before the surgery, there was already 27.4% more pain on the instrumented side (6.05 and 4.75, respectively). This difference remained until the 3-month evaluation, leaving no distinction between both sides at the 6-month visit (2.77 and 2.57, respectively).

Some adverse effects were observed during the present study. In addition to the reduction in the strength of the psoas, five patients also presented with quadriceps deficit. However, all of the patients regained both psoas and quadriceps strength, with no permanent deficit. No case has progressed to reoperation due to plexopathy. In addition to lumbar XLIF, 1 patient underwent a lateral arthrodesis at the thoracic level, and, in this procedure, the intraoperative bleeding was more pronounced (1,700 mL). However, this blood loss did not cause additional harm to the patient.

### Discussion

Interbody fusion is a widely used surgical approach for the treatment of lumbar spine degenerative diseases.\(^3\) To achieve this goal, extreme transpsoas lateral access has great applicability and biomechanical advantages over other options, mainly for maintaining the integrity of the posterior and anterior longitudinal ligaments, the latter the most important stabilizing ligament of the spine.\(^7,8\) To reach the disc space, XLIF uses the transpsoas approach, crossing between the muscular fibers. This is one of the main spinal stabilizing muscles, and it is transected by a nerve network called the lumbar plexus. To minimize the risks of nerve damage, this technique uses a directional monitoring system that evaluates the conduction of nerve impulses to the extremities, preserving neural integrity. However, even with the navigation tool, this technique still has postoperative side effects. Reduction of hip flexion strength is the main postoperative effect of XLIF. This strength is mainly performed by the psoas muscle, which is transected by dilators for disc space access. Literature studies commonly assess the frequency of this weakness in XLIF patients.\(^8–12\) This phenomenon is usually reported by the patient, and it can often go unnoticed or be overlooked. In addition, only a few papers report strength degree reductions. In a different way, the present work evaluates this parameter in a force scale in N, using measurements obtained with a dynamometer in an objective and systematic form.

In the present study, clinical parameters were evaluated in five different visits. Results showed a significant decrease of ~24% in the hip flexion strength on the ipsilateral side shortly after the surgery, returning to preoperative values 6 weeks after the procedure. Although not assessing psoas strength in the same way as the present study, Sharma et al observed a similar phenomenon of postsurgical hip flexion strength reduction, with all of the patients returning to preoperative strength values at 6 weeks.\(^8\) Similarly, other studies in the literature have also shown that hip flexion weakness is a transient phenomenon.\(^9,11\) This effect is transient since it is not a plexopathy, but a relaxation of the intrinsic innervation of the psoas itself, causing weakness, which is transitory, provided that the muscle is stimulated with regular daily activity.\(^13\)
addition to this side effect, it was observed that 8.3% of the patients presented with quadriceps weakness after the surgery as an adverse effect, a number similar to those observed in other studies in the literature.\textsuperscript{8,9,11,12}

The present study has some limitations. First, since it was conducted at a single research center, the small number of patients diminishes the power and the strength of the study. Second, the lack of data about psoas muscle retraction time from all of the patients is also a limitation, since it is not possible to directly relate this parameter with the presence of postoperative symptoms.

**Conclusion**

In summary, the present study brings a quantitative measure in a direct force scale. Thus, it does not depend on the report of the patients regarding the possible side effect of decreased hip flexion strength. This is a common side effect on the ipsilateral side due to the retraction of the psoas muscle, which is, however, transient. The patient should be instructed before surgery about the possibility of this phenomenon, to avoid possible falls—resulting from this loss of strength in the first days postsurgery—that could compromise a better postoperative result. Studies with greater casuistry are necessary to better understand these side effects and the complications resulting from lateral access.
