Compressive Neuropathy of the Ulnar Nerve in the Hypotenar Region by Lipoma: Case Report

Neuropatia compressiva do nervo ulnar na região hipotenar por lipoma: Relato de caso

Abstract

Lipomas are well-defined tumors of the adipose tissue that often occur in the torso or the extremities of adult patients. These tumors usually develop painlessly and insidiously, but they may compress adjacent structures. The objective of the present study is to describe the case of a 68-year-old female patient with a giant lipoma located at the hypothenar region, with manifestation of compression of the common palmar digital nerves, the ulnar nerve, and the abductor muscle of the V finger. Regarding the symptoms, the patient felt moderate pain in the hypothenar region, with no Tinel sign, and no changes in the motor function or sensibility of the digits innervated by the ulnar nerve. Lipomas may present a varied range of histological characteristics, and malignant tumors may be a differential diagnosis. An imaging exam may aid in the diagnosis, which is confirmed by a histopathological study. For the present case, as recommended in the literature, a surgical procedure was performed for the resection of the tumor, which resulted in the control of the symptoms.

Introduction

Lipomas usually present in adults as isolated tumors, with no presence of pain and with slow growth, more frequently in the thorax and extremities. Lipomas are typically lobular and well-circumscribed, consisting of adipose tissue cells. They are separated from the surrounding adipose tissue by a thin fibered capsule. Complementary exams are important because they assist in the determination of the type and location of the lipoma. Lipomas can be classified as intramuscular, more frequent, and intermuscular, less frequent. In addition, intramuscular lipomas are divided into infiltrative and well-circumscribed. Lipomas are commonly isolated and rarely multiple, presenting in varying shapes and sizes, being considered giant when its diameter exceeds 5 cm.

The present work aims to describe the rare case of intermuscular lipoma in the left upper limb hypothenar region with ulnar nerve compression. We also provide a brief bibliographic review on the subjects involved in the studied case. For this, we used recent material available in virtual libraries, in addition to analyzing the medical records of the patient with unusual case presentation.

First, a review of the medical records of the patient was carried out to elaborate the case report. Then, a bibliographic research was conducted in the literature, seeking papers published in the last 47 years, in Portuguese, English and Spanish. The inclusion criteria of the researched studies were: the appropriate methodology applied, the update, and the similarity in some aspect with the present case. Exclusion criteria were: low relevance of some articles, nonapproach to the area of interest, and lack of important information.

The following descriptors were used: lipoma, deepseated lipoma, lipomatous tumor, liposarcoma, lipoma of the extremities and intramuscular lipoma. The digital libraries and open access electronic data sources accessed were the Sciencifc Electronic Library Online (SciELO) and the Virtual Health Library (VHL). The portal minhaUFMG was also used to access paid articles and a theme pertinent to this research.

Case Report

Patient M. A. O., 68 years old, female, housewife, sought outpatient medical care due to persistent headache. In her physical examination, it was detected a bulging area in the hypothenar region of the left upper limb extremity. No cyanosis or phlogistic signs were observed in the bulging region. The patient reported moderate-intensity pain in the left-hand thenar region, with irradiation to digits IV and V. No Tinel sign was found on the tumor lesion, and there were no sensitivity or motricity deficits identified.

A hand ultrasonography was requested, which evidenced an echogenic nodular well-defined image, without flow to the Doppler, encapsulated, measuring 24 mm, in the hypothenar region. Upon presentation of the examination, we opted for linear incision in the V-digit axis, in the hypothenar region. Neurostimulation was performed during the procedure, in order to preserve the distal motor branches of the ulnar nerve. The lesion had a relatively well-delimited capsular structure, with a slightly oval shape and yellowish staining. After complete removal of the lesion, the common palmar digital nerves of the ulnar nerve and the abductor muscle of the V finger were identified. In the postoperative care, the patient presented pain improvement in the hypothenar region, and preservation of the motor function was confirmed.

The evaluation of the histopathologic sections of the tissue showed a benign neoplasia consisting of 12 g of unilocular mature adipose tissue, with the presence of some muscular tissue and blood vessels, interwoven by connective tissue with collagen fibers and fibroblasts, sometimes constituting a myxoid aspect. In addition, the absence of atypia and of signs of malignancy was observed.

Discussion

Lipoma is described as a benign adipose tumor, separated from the adjacent adipose tissue by a thin, well-circumscribed, well-defined film, that can occur in any region of the body. They are usually asymptomatic and are discovered incidentally during physical examination.

Fig. 1 Left hand ultrasonography evidencing a well-defined echogenic nodular image, without flow to the Doppler, encapsulated, measuring 2.39 mm, in the hypothenar region. Note the dashed lines skirting the lipoma.

Fig. 2 (a) Perioperative photo showing voluminous lesion with a relatively well-delimited capsular structure, with slightly oval shape, and yellowish staining. (B) Photography of the lesion after its resection, confirming its oval and capsulated form.
the body. When poorly circumscribed and very infiltrated, it can be mistaken for well-differentiated liposarcoma. Well-differentiated liposarcomas, in turn, do not cause metastases, and they are considered of low degree of malignancy, but they present high recurrence rates.\textsuperscript{5,6}

Among the main symptoms and signs of lipomas located in the hand are: local pain, paresis, hypoesthesia and local bulging by tumor growth in the underlying tissues (\textit{\textbf{Table 1}}).\textsuperscript{5,6}

The best form of treatment for lipomatous tumors is complete surgical resection. Surgery should be performed after complementary exams that allow the surgeon to locate the tumor and plan their approach, since precipitated measures may contribute to the recurrence of the tumor if it is not properly removed during surgery.\textsuperscript{5} Although surgery is commonly indicated, there is little consensus on which is the best surgical treatment for deep lipomatous tumors.\textsuperscript{5,7} In the literature, in the case of suspicion of malignancy, the wide resection, with margins of \textasciitilde{} 1 cm, associated with annual follow-up with complementary imaging examination, is presented.\textsuperscript{7}

Lipomas can be commonly visualized in ultrasound as distinct echogenic masses, having a varied reading; they may be: hyperechoic \textasciitilde{} 20\%–52\%), isoechoic \textasciitilde{} 28\%–60\%) or hypoechoic \textasciitilde{} 20\%).\textsuperscript{8–10} When encapsulated, the capsule may be difficult to identify in this imaging examination mode.\textsuperscript{11} In computed tomography (TC), lipomas are hypodense \textasciitilde{} 65,120 units

Magnetic resonance imaging (MRI) is often the modality of choice in the case of lipomas, not only to confirm diagnosis, which is usually suggested by ultrasound and TC, as well as better evaluating the atypical features suggesting the diagnosis of liposarcoma. In MRI, lipomas show hyperintense in sequences T1 and T2. Furthermore, magnetic resonance imaging allows a better definition of the anatomy adjacent to the tumor. The histological aspect of lipomas is characteristic, with predominant amount of adipose tissue, with adipocytes and negative image of fat. There is also the frequent presence of a fibred capsule involving the superficial region of the tumor. Less often, blood vessels are observed, often more abundant in the surrounding muscle tissue than in the tumor region, being muscular capillaries. In addition, there is a beam of muscular fibers in the middle of the tumor tissue.

Despite the range of possibilities for histological tissue types, which may vary from benign lipomas to liposarcomas, it is estimated that lipomatous neoplasms comprise half of all soft tissue tumors. Due to eventual similarities between benign and malignant affections, histological analyses have been conducted, and studies report some characteristics that allow the physician to assist in the correct diagnosis and in the efficient referral to appropriate treatment. Advanced age, tumor of high dimensions, and localization at the extremity instead of the thorax, for example, are characteristics that suggest an atypical lipomatous tumor, instead of a giant lipoma.

There are other types of lesions of a benign character that can be considered as a differential diagnosis in the present case. The importance of mentioning these tumors found in the hand is due to the complexity of the affected structures and, consequently, the implications, such as loss of sensitivity, pain or even motor impairment of the limb. In the group of lesions that could be differential diagnosis are: synovial cyst, giant cell tumor of the tendon sheath, cysts of epidermal inclusion, fibromas, Schwannomas and neurofibromas.

A table was elaborated relating rare and representative lipoma cases (Table 1). Most of them present mild symptomaticology and/or presence of local bulging without symptoms. Rare cases developed with neurological manifestations, and all revealed resolution of the pain and motor symptoms when present.
