Dr. Monica Sharma

ABSTRACT

Aim- 1. The aim of this study was to investigate the average maximum range of inter-incisal mouth opening in a representative sample of the adult subjects of Haryana. 2. To see any correlation between maximal inter-incisal opening with age.

Methods- Maximum mouth opening was studied in 756 adult subjects with age range of 20-50 years in Yamunanagar, Haryana. Age limit was further divided into three groups (20-30, 31-40, 41-50). Those with clinical history of TMJ involvement, OSMF, any trauma, odontogenic and non-odontogenic infections, dental prosthesis on the anterior teeth, congenital anomalies in the maxillofacial region were excluded from this study. The measurements were recorded twice and mean of the two values were taken.

Statistical Analysis- Independent sample t-test was calculated to compare age and mouth opening in both male and females respectively. Bivariate pearson correlation was used to see any relationship between age and mouth opening. P-value ≤0.05 and CI (confidence interval) at 95% were considered statistically significant.

The Results- The average mouth opening of males (45.36± 6.70 mm) subjects was higher as compared to female (41.27± 6.75 mm) with significant, p-value 0.000. The mean mouth opening ± SD for both sexes combined was 43.39 ± 7.02 mm. The corresponding values for mean inter-incisal opening in male population aged 20-30, 31-40, 41-50 were 45.52 ± 7.15, 46.16 ± 5.47, 42.96 ± 6.82 mm and in female population aged 20-30, 31-40, 41-50 were 41.40 ± 7.08, 41.60 ± 6.29 and 40.03 ± 6.38 mm respectively.

Conclusion- Maximal mouth opening differs significantly with gender. There is a decrease in MMO with older age group.

Key words: Maximum mouth opening, Range of motion, Temporomandibular joint disorders (TMD), Oral Sub Mucous Fibrosis (OSMF).

INTRODUCTION:

Mouth opening assessment is an important part of every clinical examination in dentistry. However, few studies of the normal range of maximal mouth opening have been undertaken in different ethnic group of Indian population. With limited availability of data on normal range of mouth opening, there remain a gap in clinical examination of patients particularly with Temperomandibular disorder (TMD), (Oral Submucous Disorder) and with dysfunction of other masticatory disorder.

The greatest distance between the incisal edge of the maxillary central incisors to the incisal edge of the mandibular central incisors at the midline when the mouth is open as wide as possible is defined as the interincisal opening 1.

One of the important factor in determining the function of the temporomandibular joint (TMJ) and the masticatory muscle status is the jaw opening capacity 2. Therefore the range of mandibular movement is a valuable measure in the diagnosis of patients with suspected functional disorders of the masticatory apparatus 3.

Restricted mouth opening may occur due to intra or extracapsular pathology of TMJ 4,5,7, head and neck cancer patients 6,9,10, iatrogenic causes such as third molar extractions, hematomas secondary to dental infection and delayed effect of intermaxillary fixation after mandibular fracture or other trauma 11.

AIM OF THE STUDY

1. To determine the maximum normal mouth opening in the studied population so as to establish a normal range of mobility which can useful as an indicator of the function of TMJ and the masticatory system.

2. To investigate any correlation between age and Maximum mouth opening (MMO) both in male and female.

METHODOLOGY

Over a period of 10-month, a survey was undertaken at the concerned hospital to estimate the maximal inter-incisal opening of normal adult population. The proposed study included 756 patients (392 male and 364 female) which were randomly selected from concerned hospital. Patients was divided further into three age groups - 20-30, 31-40, 41-50.

Consent was taken from the ethical committee and all the participants were informed about the objective and the purpose before conducting the study. Those patients who had no history of TMD, had functional occlusion with no

extrusive interferences and had intact dentition were included in the study. Patients that were excluded from the study were those with a history of -

- Temporomandibular dysfunction.
- Trauma.
- Bruxism.
- Patients with anterior teeth missing (central incisors) / dental prosthesis.
- Any acute odontogenic and non-odontogenic infections associated with pain/burning sensation
- Congenital facial anomaly
- Patients with oral submucous fibrosis.

The information was collected through questionnaire given to the patients. Selections of the subjects for the study were finalized after reviewing of the questionnaire by the experts. A through intra oral, extra oral and TMJ examination was done and the inter-incisal opening was measured by using geometric divider and millimeter ruler as a study instrument. Each patients was seated comfortable on a dental chair and was asked to open the mouth as wide as possible. The maximum distance was measured from the incisal edge of the maxillary central incisors to the incisal edge of the mandibular central incisors at the midline. The value was measured in millimeters. The examination and the measurement were performed by a single examiner to avoid any bias in the study.

STATISTICAL ANALYSIS

Linear measurements of quantitative data like age (years) and mouth opening (mm) are presented in mean ± SD along its maximum and minimum values. Independent sample t-test was calculated to observe any significant differences in mouth opening in both male and females respectively. Bivariate pearson correlation was used to see any relationship between age and mouth opening. P-value ≤ 0.05 and CI (confidence interval) at 95% were considered statistically significant.

THE RESULTS

Out of the 756 patients (392 male and 364 female), mean ages of all subjects was 31.53 ± 7.95, with age range 20-50 years. Moreover, the mean age ± SD for both male and female subject were 31.07 ± 7.67 and 32.04 ± 8.26 respectively. The mean inter-incisal opening ± SD for both sexes combined was 43.39 ± 7.02 mm. The mean inter-incisal opening of males (45.36 ± 6.70 mm) subjects was higher as compared to female (41.27 ± 6.75 mm) with significant, p-value 0.000.

The corresponding values for mean inter-incisal opening in male population aged 20-30, 31-40, 41-50 were 45.52 ± 7.15, 46.16 ± 5.47, 42.96 ± 6.82 mm and in female population aged 20-30, 31-40, 41-50 were 41.40 ± 7.08, 41.60 ± 6.29 and 40.03 ± 6.38 mm respectively.

The maximal inter-incisal opening was highly significant and negatively correlated with age; this indicates that there is decrease in mouth opening with increasing age (r = -0.121 with p-value as 0.000 , less than 0.01). Similarly, in male and female population ages was significantly negative correlation with mouth opening (r = -0.114 with p-value = 0.024) in male and in female an insignificant moderate negative correlation (r = -0.102 with p = 0.052) were observed.

DISCUSSION

A high frequency of limited mouth opening is observed in dental clinical practice. However, few studies of normal range of mouth opening have been undertaken in Indian population. The normal range of mouth opening in different geographical or ethnic variation seems to be overlooked.

Maximum mouth opening were observed in males than females. This may be because the mouth opening depends upon the size of the mandible which is greater in males than female as done in a study by Scavone H et al (2006). Measurements of maximal mouth opening may vary from 40-77mm in male and 32-75 mm in female subjects.

A difference in mouth opening among genders has been reported with man having tendency to open on average five mm more than women. Similar results was observed in this study with man having tendency to open more with an average 45.36 mm (range 52.06-38.66) as compared to female 41.27 mm (range 48.02-34.52).

In this present study maximal inter-incisal opening decreases significantly with ageing in both male and female. This findings agrees with the findings done by Aqibsohail and Amjad A (2011) in Pakistani population, Gallagher et al (2004) in Irish population and Yao KT and Lin C (2009) in Chinese population. This may be due to changes in TMJ as a part of normal ageing process. To meet the functional demand, condylar remodeling, a physiological process occurs to adapt the structure of the temperomandibular joints (TMJ). In a study done by Mathew AN, 2011, an statistically significant increase in radiographic changes in condylar morphology was observed with increase in age.

Among the three age groups (20-30, 30-40, 40-500) highest inter-incisal opening was observed in middle age
group (30-40) and lowest inter-incisal opening in older age group (40-50). Similarly, in a study by Mezitis M et al in Greek population, aged 18-70, greatest mouth opening was recorded in younger age group (18-30) both in male (56.6 mm) and female (51.0 mm). The lowest measurements were in older age group 51-60 years in male (51.0 mm) and 61-70 years in female (44.5 mm).  

Similarly, in a study by Mezitis M et al in Greek population, aged 18-70, greatest mouth opening was recorded in younger age group (18-30) both in male (56.6 mm) and female (51.0 mm). The lowest measurements were in older age group 51-60 years in male (51.0 mm) and 61-70 years in female (44.5 mm).  

Majority of studies had demonstrated changes in mouth opening with age and gender. However, variation in changes is due to ageing remain unclear. Further survey should be perform in larger sample size in different regions of Indian population.

**CONCLUSION**

Within the limits of this study, we conclude the following points:

1. MMO differ significantly with gender.
2. There is a decrease in MMO with older age group.

This results agrees with the studies reported in different countries.
