Abstract

Background and Objective  The carotid canal (CC) is a bent passage in the petrous temporal bone from where the internal carotid artery (ICA) goes inside the skull. The shape, location and measurements of the CC are clinically very important in cases of skull base surgery, since the ICA has to be identified and isolated throughout its petrous course. Therefore, the present study was performed to measure and locate the CC from various important anatomical landmarks.

Materials and Method  The present study was conducted on 68 dry skulls of unknown gender. Various measurements and distances of the CC from various important landmarks were taken. The shape of the CC was also noted. Measurements were taken with the help of a screw-adjusted compass and of digital Vernier calipers. From the above measurements, mean and standard deviation (mean ± SD), median, range, and mode were calculated. Data analysis was done with IBM SPSS Statistics for Windows, Version 19.0 (IBM Corp, Armonk, NY, USA).

Results  The mean length of the CC on the right and left sides was 7.76 and 7.89 mm, respectively. The mean breadth of the CC on the right and left sides was 5.81 and 6.32 mm, respectively. The most common shape of the CC was round both on the right and left sides in 49.20% and in 53.12% of the cases.

Conclusion  The results of the present study will be useful in the performance of neurosurgical procedures, thereby preventing unpleasant complications.

Introduction

The carotid canal (CC) is a large, almost circular foramen through the petrous part of the temporal bone, through which the large vessel internal carotid artery (ICA), along with accompanying plexuses of veins and some autonomic nerves are transmitted. The external aperture of the carotid canal (EACC) is seen on the undersurface of the petrous part of the temporal bone, posterolateral to the foramen lacerum and anterolateral to the jugular foramen.1,2 Starting from the EACC, the CC runs up for a distance of 1 cm and then bends at around 90°. The CC turns forward and toward the medial side, up to the apex of the petrous part of the temporal bone for about 2 to 3 cm and then ends, forming the internal aperture of the carotid canal (IACC). This opening is found in front of the foramen lacerum, and the ICA enters the cranial cavity. The ICA is separated from the walls of the CC by the internal carotid venous plexus and by some perivascular tissue.3

Measurements of the base of the skull in adults have been performed by very few investigators. Some previous researchers have studied the IACC, while some have also
measured the size of the CC in adults along with measurements of the angles of the internal bend of the CC. Normal and abnormal findings regarding the foramina of the skull can be revealed by investigations such as computed tomography (CT) and magnetic resonance tomography (MRT). Precise information about the anatomy of the base of the skull has become critical as various microsurgeries have been employed for certain tumors and aneurysms. The present study can provide data to neuroradiologists and neurosurgeons about the comparison of the measurements of the base of the skull. The CC was selected as the landmark as it is the most important and easily identifiable structures on MRT and on digital subtraction angiography (DSA) exams. Therefore, regarding the ICA and its associated anomalies, we intend to give population-specific details of the CC which would assist neurosurgeons to improve different surgical approaches to the second part of the ICA i.e. petrous part.

Materials and Methods

A total of 68 dry skulls of unknown gender were used for the present study. Skulls which were damaged, fractured or deformed at the surroundings of the CC were eliminated from the study. The following parameters were measured: (Figs. 1 and 2)

1. Anteroposterior diameter of the CC (L)
2. Transverse diameter of the CC (B)
3. Shortest distance from the CC to the external acoustic meatus (EAM).
4. Shortest distance from the tubercle of root of zygoma (ZA) to the CC
5. Shortest distance from the tip of the mastoid process (MP) to the CC
6. Shortest distance from foramen magnum (FM) to the CC
7. Shortest distance from the occipital condyle (OC) to the CC
8. Shortest distance from the midline of the base of the skull (Mid) to the CC

The shape of the CC was also noted. All of the measurements were taken on both sides. The measurements were taken with the help of a screw-adjusted compass and of digital Vernier calipers. All of the measurements were taken three times by the same person in order to increase the accuracy of the measurements.

Statistical Analysis

From the above measurements, mean and standard deviation (mean ± SD), median, range, and mode were calculated. The data analysis was performed with IBM SPSS Statistics for Windows, Version 19.0 (IBM Corp, Armonk, NY, USA), and p < 0.05 was considered statistically significant.

Results

A total of 68 skulls were examined. Five skulls were not examined on the right side, and four were not examined on the left side due to destruction. Therefore, the total number of sides examined was 127.

The results of the measurements of the CC are shown in Table 1.

The mean, median, and range of the distances from the CC to various important anatomical landmarks were tabulated as shown in Table 2.

The various shapes of the CC were noted down and tabulated in Table 3. (Fig. 3)

Discussion

The ICA arises from the common carotid as a bifurcation at the superior border of the thyroid cartilage opposite to the disc between the C3 and C4 vertebrae. Each artery passes upward through the neck within the carotid sheath, toward the brain. The artery is divided into four parts along its course: the cervical, petrous, cavernous, and cerebral parts.
The ICA traverses the petrous part of the temporal bone in the CC, in which it first passes upward along the anterior wall of the middle ear cavity and the cochlea of the internal ear, and then curves forward and medially below the auditory tube and the trigeminal ganglion. It enters the cranial cavity through the apex of the petrous temporal bone in the posterior wall of the foramen lacerum.\(^5\)

Fractures of the base of the skull are commonly associated with carotid artery injuries, and vascular complications are more frequently observed when the CC is involved. Fractures at the petrous part of the CC are associated with a relatively high incidence of injury to the carotid artery, and patients suffer more severe head injuries.\(^6\) In < 0.01% of the population, rare congenital anomalies like a non-formed or a poorly formed ICA can be seen. However, agenesis of the ICA is usually asymptomatic and is usually found as an incidental finding or after a cerebrovascular accident, such as

subarachnoid hemorrhage after a coincidental rupture of an aneurysm, or cerebral infarction.\textsuperscript{7,8} This is commonly seen unilaterally; however, bilateral absence has been reported. Also, the estimated prevalence of cerebral aneurysms in association with agenesis of ICA is of between 24 and 34% in the general population, and recognizing this anomaly is of great value in thromboembolic cases.\textsuperscript{7} Although the exact cause of these developmental anomalies is not known, the evaluation of the base of the skull for the absence or presence of the CC is required to differentiate agenesis and aplasia, as the prerequisite for the development of the CC is the presence of a precursor of the ICA or of the ICA itself at a gestational age of 5 to 6 weeks. This development of the bony CC represents the development of the ICA, which may end as the stenosis of the ICA begins and poorly formed bony carotid canal can be seen in adult onset moyamoya disease patients.\textsuperscript{9}

During the intruterine development, before the mesenchymal condensation starts to initiate to form the cranial cartilages, the major cranial blood vessels and nerves are already formed. Therefore, the foramina of the skull are specifically placed even before the formation of bones. Mesenchymal chondrogenesis around the carotid artery joins each hypophysial cartilage to the otic capsule, to form the CC.

Congenital agenesis of one or both ICAs has a very high association with aneurysm formation in the circle of Willis, and since the CCs in the skull base form after the formation of the embryonic ICA, agenesis, aplasia or hypoplasia of a CC on a computed tomography (CT) scan of the base of the skull would suggest a congenital abnormality in the ICA and hint at an investigation for any other associated intracranial vascular abnormalities, even in a young or asymptomatic patient.\textsuperscript{10} Therefore, the present study was conducted to provide some data on the differences in the morphology of the bilateral vascular opening for the ICA, which is the CC. Regarding the ICA, the importance of measurements of the CC has been previously estimated by various authors with the aim to improve various surgical approaches to this part of the ICA.\textsuperscript{11} There is a rapid development of the bony structure of the CC before around the age of two years old, and after the bony suture fuses, the development slows down. Also, the inexistence of the anteroinferior wall of the CC bilaterally was first reported in 1896. The absence or the deficiency of the inferior wall of the CC is a vital disparity which can lead to complications in surgeries of the base of the skull.\textsuperscript{12} Previous studies have reported the absence of the inferior wall of the CC, which had an incidence of only 1 in 325 cases, while in other studies, 5 cases were found in 307 skulls.\textsuperscript{13,14}

The measurements of the CC are noted in previous studies, such as the one by Watanabe et al., and the transverse diameter in normal Japanese adults was of 5.27 ± 0.62 mm, whereas it was shorter (3.31 ± 0.44 mm) in patients with adult-onset moyamoya disease with ICA stenosis.\textsuperscript{9}

The comparison of our parameters with the parameters of other authors is shown in Tables 4, 5 and 6.\textsuperscript{5,15–17}

Calguner et al have also obtained measurements of CCs from 307 dry skulls, including 177 adult male and 130 adult female skulls, and the values of the mean anteroposterior diameter of the carotid canal were 6.82 ± 1.56 and 6.50 ± 1.46 (Mean ± SEM) on the right and left sides of male skulls, respectively. In the female skulls, these values were 6.68 ± 1.18 and 6.30 ± 1.05 on the right and left side.

</table>
respectively. The mean transverse diameter on the right and left side of male skulls were 4.86 ± 2.34 and 4.60 ± 1.05, respectively. In the female skulls, these values were 4.59 ± 0.87 and 4.33 ± 0.91 on the right and left side, respectively. In another study by Lang et al, the mean anteroposterior diameter of the CC was 5.08 ± 0.20 and 5.20 ± 0.34 on the right and left sides of the skulls, respectively. However, in both of these previous studies, the measurements of the anteroposterior (long) diameter and of the transverse (short) diameter of the internal opening of the CC were taken, while in the present study the measurements of the external aperture of the CC were taken.

In a previous study by Calguner et al, the values of the distance from the medial end of the external opening of the CC to the midsagittal plane are 2.50 ± 3.59 and 24.92 ± 2.45 on the left and right sides for females, respectively, and 25.63 ± 3.60 and 25.67 ± 2.88 on the left and right sides for males, respectively. In another study by Lang et al, these values were 20.50 ± 0.50 and 24.25 ± 0.75 on the left and right sides, respectively.

**Conclusion**

Our study provides important information about the site of the CC using various anatomical landmarks surrounding it in the bases of the skulls of adult Indians. These linear dimensions will facilitate neurosurgical procedures, thereby preventing unpleasant complications.

Conflicts of Interests

We state that we did not receive any financial funding from any agencies. The authors have no conflicts of interests to declare.
