Introduction

The flexor carpi ulnaris muscle (FCUM) originates from two slips: one from the olecranon and another from the medial epicondyle of the humerus; these muscle bands fuse and forms a fleshy muscle with a strong tendon that inserts itself onto the pisiform bone.1,2

The FCUM is innervated by the ulnar nerve (UN), which lies between these fasciculi before they fuse, and it is accompanied by the posterior ulnar recurrent artery. FCUM allows the hand to flex over the forearm and has a slight adductor function.1,3

Although variations of the FCUM are rare, it is a clinically significant muscle, as it can cause compression of the UN, and it can be used as a muscle flap for soft tissue reconstruction.4–6

Variations of the forearm muscles are well described in the literature. In spite of that, reports regarding the accessory flexor carpi ulnaris muscle are scarce due to its rarity. This muscle usually originates from the medial epicondyle of the humerus with the flexor muscle mass and inserts itself into the palmar aponeurosis or the pisiform bone together with the flexor carpi ulnaris muscle. Supernumerary and anomalous muscles of the anterior compartment of the forearm have been associated with ulnar nerve and artery compression. Furthermore, they may also mimic neuromas and soft tissue tumors. The study of supernumerary muscles is necessary, as they may be an option to tendon grafts and muscle flaps. The aim of this paper is to describe the presence of the accessory flexor carpi ulnaris muscle on the left forearm of a cadaver fixated in a phenol solution and discuss its clinical and anthropological significance.

Case Report

A male cadaver fixated in a phenol solution was dissected for teaching purposes. The presence of a supernumerary muscle was observed, which was identified as an aFCUM in his left forearm. There were no other associated variations on any side.
The aFCUM was located medial to the FCUM and lateral to the palmaris longus muscle. Its proximal tendon originated from the medial intermuscular septum together with adjacent muscles, and its distal tendon inserted itself into the flexor retinaculum (Fig. 1). This accessory muscle had a fusiform shape and measured 19.8 cm in length.

The ulnar artery and nerve were covered by this accessory muscle during their entire trajectory of the forearm. The floor of the Guyon canal was reinforced by the distal tendon of this muscle (Fig. 1). It was innervated by branches of the UN.

**Discussion**

Development of the muscles starts with segmentation of the paraxial mesoderm into somites. Each somite has two portions: the sclerotome (which gives origin to bones and cartilages of the thorax and vertebral column) and the dermomyotome (which will form the muscles).

The myotomes give origin to myoblasts, which go through extensive migration in order to originate the limb muscles. This process starts during the fifth week of development. Then, all myoblasts condense and fuse to form 2 distinct muscle masses on the forearm: the ventral and the dorsal. The ventral mass forms the flexors and pronators, while the dorsal mass forms the extensor and supinator muscles of the forearm.

Through apoptotic mechanisms and growth factors, each muscle begins to take its shape and current appearance. The presence of supernumerary muscles is usually caused by an increase of cell stimuli, which causes proliferation of muscle tissue and the lack of apoptotic stimuli to cease its growth.

The FCUM is a fairly consistent muscle that rarely varies (0.02% of all flexor compartment variations). Aberrant origin or insertion, additional slips, partial muscle belly, split tendon, fusion with palmaris longus muscle and the presence of an aFCUM are among reported variations of the FCUM.

According to Le Double (1897), the aFCUM was first described by Jarjavay in 1857. Variations regarding the insertion onto the metacarpals and their joints can be interpreted as regressive dispositions of mammals such as koalas, hyenas and sloths.

Moreover, the ulnar slip of the FCUM is absent in pigs and is in a fibrous state in tapir (Tapiridae tapirus). The proximal portion of the FCU is blended with the palmaris longus muscle in rats. Its tendon is bifurcated in dogs. Those patterns represent the fact that numerous variations of the FCUM in humans possess similarities with other those of mammals and animals from other species.

Clinically, the presence of supernumerary or abnormally large muscles on the forearm may be the cause of neurovascular bundle compression. The length, girth, width and the relations of the aFCUM reported herein could predispose an individual to develop compressive neuropathies of the UN not only on the Guyon’s canal, but in the whole forearm instead. In addition, the distal insertion on the flexor retinaculum by the aFCUM could compromise the median nerve as well. Furthermore, The aFCUM may simulate a ganglion or a soft tissue tumor. The ulnar artery could also be a target to compression, as the presence of more muscle mass in the fascial compartment would cause more pressure on this vessel, thus, provoking a decreased local blood flow either during forearm flexion or even in stationary position.

The clinical diagnosis of an accessory muscle belly should be kept in mind when there is a soft and palpable mass at the wrist associated with flexion deformities, albeit not a constant symptom.

Diagnosis often requires imaging techniques, such as CT-scan and MRI. Despite that, most of the muscle anomalies of the forearm are found during surgery or cadaveric dissection. Hence the importance of reporting anatomical variations to provide knowledge and further expand the surgeon’s awareness.

Furthermore, the FCUM has been used as local and free muscular flap in soft-tissue reconstruction surgery, as well as...
in tendon transfer procedures.\(^5\) As the tip of the olecranon has a thin and movable skin, postoperative complications of total elbow arthroplasty are not uncommon. In light of this, FCUM flap has been performed recently due to its regular vascular supply and easy flap obtainment from this muscle.\(^6\) Thus, an aFCUM would also be a good candidate for this procedure, despite its rarity in the general population.

In conclusion, the aFCUM is a clinical and surgical significant variation that should be further studied despite its rare incidence. Nerve compression caused by supernumerary muscles is well described in the literature, specifically in the forearm-hand complex, as the muscles are more prone to vary and the nerves are more exposed due to their relations with the adjacent structures. Supernumerary muscles of the forearm may also confuse diagnosis of soft tissue tumors and neuromas.

Conflicts of Interest
The authors have no conflicts of interest to declare.
