Abstract

Crizotinib is an anaplastic lymphoma kinase (ALK) inhibitor, used as a targeted chemo-therapeutic agent in ALK-positive cases of nonsmall cell lung carcinoma. Although uncommon, it may be associated with the formation of new renal cysts, which may be simple or complex, or the enlargement of preexisting simple renal cysts or their transformation into complex cysts. These cysts usually regress partially or completely but may rarely enlarge over time or get complicated by infection or abscess formation. Such cases may even require dose reduction or withholding crizotinib. Although documented in clinical literature, this entity is not well known among radiologists. Knowledge of this entity helps in preventing erroneous diagnosis of the new kidney “lesion” as metastasis or disease progression and avoids an unnecessary biopsy. We describe a series of four cases which developed complex renal cysts during treatment with crizotinib to demonstrate this point.

Keywords
► crizotinib-associated renal cyst
► anaplastic lymphoma kinase
► nonsmall-cell lung cancer
► complex cyst

Introduction

Nonsmall-cell lung cancer (NSCLC) constitutes 85% of all lung cancers.1 Rearrangements of the anaplastic lymphoma kinase (ALK) gene are present in 3 to 5% of NSCLCs.2 Crizotinib is a first-generation orally active ALK inhibitor, which has revolutionized the treatment of ALK-positive NSCLC since receiving Food and Drug Administration approval in November 2013.

The development of renal cysts as an adverse effect of crizotinib has been described since clinical trials in 2011, with a reported incidence of 4 to 42%.3-7 With crizotinib assuming the center-stage in the treatment of NSCLC, the radiologist needs to be familiar with this entity so as to avoid misdiagnosing a new renal "lesion" as a metastasis. In this case series, we describe the imaging appearance and evolution of renal cysts in four cases of ALK-positive NSCLC treated with crizotinib at our institute.

Case Reports

1. A 64-year-old man was diagnosed with metastatic ALK-positive adenocarcinoma of the lung. He was started on crizotinib. In the baseline scan, both the kidneys were normal (►Fig. 1A). Two months after initiation of crizotinib, the response assessment computed tomography (CT) scan (►Fig. 1B) revealed a new complex cystic lesion in right kidney, which almost doubled in size in next 3 months (►Fig. 1C). The patient’s primary and metastatic disease otherwise responded well to the chemotherapy. This was correctly identified as a crizotinib-associated complex renal cyst and remained stable through the rest of therapy.

2. A 57-year-old woman with ALK-positive metastatic large cell neuroendocrine carcinoma was started on crizotinib. Response assessment CT scan done after 1 month (►Fig. 2A) showed a new thick-walled cystic lesion in left kidney. This was labeled a crizotinib-associated renal cyst (CARC) and followed up. The renal lesion remained stable after the subsequent follow-up scans (Fig. 2B). There was partial response of the primary tumor.

3. A 40-year-old woman with ALK-positive metastatic NSCLC was started on crizotinib. Both kidneys were normal in the baseline scan. On follow-up CT after 2 months (►Fig. 3A1 and A2), two new complex cystic lesions were seen, one each in either kidney.

After 4 more months, she developed flank pain and fever spikes. CT scan showed massive increase in the size of both the renal lesions with abscess formation and invasion into the renal bed (►Fig. 3B). Both the lesions were drained...
Aspirated fluid was negative for malignancy. The dose of crizotinib was halved and empirical broad-spectrum antibiotics were started; however, the symptoms did not resolve. It was decided to withhold crizotinib in view of nonresolving infection.

Subsequent CT scan done after 2 months demonstrated near complete resolution of the bilateral renal lesions and perirenal inflammatory changes (Fig 3C). The patient was restarted on crizotinib after 3 more months at a lower dose. Unfortunately, this again led to an increase in the size of bilateral renal lesions and the formation of a large right iliopsoas abscess (Fig 3D). The abscess was drained by pigtail insertion and crizotinib was stopped till symptomatic improvement and then reinitiated. The patient is stable on follow-up since then.

4. A 57-year-old man, diagnosed with ALK-positive metastatic adenocarcinoma lung, was started on crizotinib in June 2017. The baseline CT showed unremarkable kidneys. On CT scan done after 3 months (September 2017), new simple cysts were seen in left kidney (Fig 4A). On 6 months (December 2017) follow-up scan, the cysts showed increase in size (Fig 4B). The patient was asymptomatic for any renal issues and is on routine follow-up.

Scan Protocol
Please note that these cysts were identified on routine follow-up CT done for these patients. CT scans were performed on 16 slice Siemens Somatom emotion CT scanner, manufactured in Erlangen, Germany. Following parameters were used to perform the contrast-enhanced CT scan: collimation, 4 × 2.5 mm; slice thickness, 1.5 mm; reconstruction interval, 1.5 and 5 mm; table feed, 12 mm/rotation. Kilovolt potential and milliampere seconds were adjusted in each case by using the automatic exposure control. Patients were given intravenous noniodinated contrast medium, either Ultravist (iopromide 300) or Omnipaque (iohexol 300) at a dose of 1.2 mL/kg body weight with the scan performed at 70 seconds after the injection, using automatic pressure injector at a flow rate 2.8 mL/s.
Discussion

The historical standard of care for treating NSCLCs has been platinum-based double agent chemotherapy. However, there has been paradigm shift in the treatment of NSCLC in the last decade, as a result of significant advances in molecular pathology and better understanding of heterogeneous tumor biology. Specific oncogenic driver mutations have been identified that lead to uncontrolled tumor proliferation, with epidermal growth factor receptor (EGFR) mutation being the most common, followed by ALK mutation. Targeted therapeutic agents have been developed to target these mutations by either small molecule inhibitors or receptor monoclonal antibodies. The successful targeted inhibition of these using EGFR tyrosine kinase inhibitors and crizotinib respectively has revolutionized the treatment of adenocarcinoma lung, with significantly improved progression free and overall survival in these patients.

The association between crizotinib and development of renal cysts has been known since the drug was in phase III clinical trials. However, its pathogenesis is still not clearly understood. Tyrosine kinase receptor (c-mesenchymal to epithelial transition) is normally present in renal tubular epithelium and their inhibition by crizotinib could represent the responsible pathway.

Crizotinib-associated cysts are usually simple but can be complex. They can present in the form of de novo appearance of new cysts, or as enlargement or increased complexity in preexisting cysts. The incidence of the various patterns of crizotinib-associated cysts as reported in literature is summarized in Table 1. By far, the dominant pattern of evolution of CARCs is asymptomatic cysts that enlarge and spontaneously regress without the need for discontinuation of crizotinib or intervention. In our cases, the patients had stable cysts or progressively enlargement of cysts or transformation into complex cysts, without any impairment in renal function.

Although ultrasonography (USG) can detect and characterize these cysts, CT usually forms the mainstay in characterization of these lesions, as it is anyway performed for response assessment in patients on crizotinib. On USG, CARCs may appear as ovoid, anechoic lesions with smooth well demarcated walls. Internal echoes and septations may be present in complex cysts and may sometimes cause a “pseudosolid” appearance. In such cases, posterior acoustic enhancement and lack of internal vascularity would favor complex cysts.

Similarly, CT may demonstrate a simple or complex cyst. It is important to obtain pre- and postcontrast images so that calcifications and hemorrhage can be accurately identified, and high-density nonenhancing renal cysts are not mistaken as solid metastases. Simple cysts are near water density with an upper threshold of 20 Hounsfield units (HU). Complex features include hyperdense contents, septations, mixed solid cystic appearance, poorly defined margins, or extension into renal bed. The two commonest complex features in these CARCs are the development of multiple septations and a mixed cystic and solid appearance. The apparent solid appearance of some of these cysts may be due to the underlying inflammatory process. These cysts can fall into categories III, IV, and IV of Bosniak classification. It must be remembered that although Bosniak III/IV cysts usually need surgical resection, crizotinib-associated complex cysts are not known to have malignant potential and therefore resection is not recommended.

The differential diagnosis of renal cysts demonstrating complex features in a patient with NSCLC includes infections such as pyelonephritis and renal abscess, renal metastases, and primary renal malignancy. Infection can be excluded clinically based on lack of symptoms and urinalysis. Renal metastasis and primary renal neoplasm are rare; knowledge of CARC is, however, essential to avoid misinterpretation. Metastasis can have similar imaging morphology as the primary lesion in lung. Renal metastases have been described as small, multiple, bilateral, and located within the renal capsule. Delayed contrast-enhanced CT can help to distinguish renal cell carcinomas (RCC) and non-neoplastic cysts by measuring decrease in HU on delayed phase. RCC shows significant decrease in HU on delayed phase as opposed to benign cysts which remain unchanged. CT and magnetic resonance imaging findings of complex cysts are similar; no significant difference is present between the two modalities in characterization of these lesions.

Our case series highlights the importance of recognizing the imaging features of new renal cysts as an adverse effect of crizotinib treatment. Misinterpretation of such complex cysts as metastasis or disease progression may lead to futile invasive investigations, or worse, may lead to cessation of an otherwise effective chemotherapy. In cases in which complex renal cysts extend into adjacent extrarenal spaces, percutaneous drainage becomes necessary to hasten resolution. Existing case reports in literature and our own experience suggest that stopping crizotinib leads to their spontaneous regression.

Conclusion

Development of renal cysts is not an uncommon side effect of treatment with crizotinib. Cysts are typically benign and remain stable on continued crizotinib therapy. They may, however, rarely enlarge over time or get complicated by infection or abscess formation. Such cases may even require dose reduction or withholding crizotinib. Complex cysts can mimic infection, primary renal malignancy or metastasis, or Bosniak III/IV category cysts. It is imperative that radiologists are aware of this entity in order to avoid wrong interpretation and mismanagement.
