Abstract

Background Even after successful aortic coarctation (CoA) repair, hypertension causes premature morbidity and mortality. The mechanisms are not clear. The aim was to evaluate elastic wall properties and aortic morphology and to correlate these results with severity of restenosis, hypertension, aortic arch geometry, noninvasive pressure gradients, and time and kind of surgical procedure.

Methods Eighty-nine patients (17 ± 6.3 years) and 20 controls (18 ± 4.9 years) were examined using magnetic resonance imaging (MRI). In addition to contrast-enhanced MR angiography and flow measurements, CINE MRI was performed to assess the relative change of aortic cross-sectional areas at diaphragm level to calculate aortic compliance (C).

Results Fifty-four percent of all patients showed hypertension (> 95 th percentile), but more than half of them had no significant stenosis (defined as $\geq 30\%$). C was lower in CoA than in controls (3.30 ± 2.43 vs. 4.67 ± 2.21 [$10^{-5} \text{ Pa}^{-1} \text{ m}^{-2}$]; $p = 0.024$). Significant differences in compliance were found between hyper- and normotensive patients (2.61 ± 1.60 vs. 4.11 ± 2.95 ; $p = 0.01$), and gothic and Romanesque arch geometry (2.64 ± 1.58 vs. 3.78 ± 2.81 ; $p = 0.027$). There was a good correlation between C and hypertension ($r = 0.671$; $p < 0.01$), but no correlation between C (and hypertension) and time or kind of repair, restenosis, or pressure gradients.

Conclusion The decreased compliance, a high rate of hypertension without restenosis, and independency of time and kind of repair confirm the hypothesis that CoA may not be limited to isthmus region but rather be a widespread (systemic) vascular anomaly at least in some of the CoA patients. Therefore, aortic compliance should be assessed in these patients to individually tailor treatment of CoA patients with restenosis and/or hypertension.

Introduction

Aortic coarctation (CoA) is a common congenital malformation with an incidence of 8 to 10/10,000 and is therefore one of the five most frequent congenital heart diseases. Patients with an uncorrected CoA have a mean life expectancy of only 35 years.¹ Surgery has been available to repair this defect since more than half a century and now interventional catheter methods of treatment are available. CoA therapy during early childhood should prevent progressive cardiac failure and reduces the risk of later hypertension^{2–4}. While often considered to be cured, patients with repaired CoA frequently have premature morbidity and even mortality.⁵ Long-term follow-up studies showed, that also these patients have a reduced life expectancy. In previous studies, 50 years after surgery, only little more than two-thirds of the patients are alive,^{6–8} and in the COAFU trial, the late mortality rate was 6% with a median age of 41 years.⁹ Systemic arterial (residual or recurrent) hypertension has been proposed as the major reason for premature morbidity and mortality after aortic CoA repair due to cardiovascular complication.^{2,3,7,8,10–12} The pathophysiology of hypertension that occurs also late after CoA repair is not yet fully understood. Hypertension may be associated with anatomical and functional changes in the arterial vasculature. Restenosis or residual stenosis accounts for only a minority of cases of postoperative hypertension.^{5,13,14} Systemic hypertension can occur after repair and may be due to residual or recurrent coarctation, but even patients with a successful repair may develop hypertension.

It was hypothesized that abnormalities of the aortic wall may impair aortic elasticity and compliance. This idea is consistent with other findings of a stiffer transverse aortic arch in patients with CoA and suggests that the defect may not be limited to the small area of coarctation but may be a widespread vascular anomaly.¹⁵

The aim of this study was to assess the prevalence of abnormal elastic wall properties in patients after CoA repair (remote of the region of any treatment/intervention) and aortic arch geometry, and second, to evaluate the relation of these results with the severity of restenosis, hypertension, noninvasive pressure gradients, and time and kind of surgical procedure.

Materials and Methods

Patients

Eighty-nine patients (mean age 17 ± 6.3 years; median 7, range 3–37 years: end-to-end anastomosis [$n=45$], patch plastic [15], subclavian flap [9], others [20]: 40% treated in first year of age) and 20 controls (18 ± 4.9 years) were examined prospectively.

Over a period of 10 years (between June 2002 and March 2012 a total of 192 patients with CoA were operated), 89 patients with previously surgically repaired CoA ($n=79$; 89%) or native CoA ($n=10$; 11%) were included in this prospective study. There were 59 males and 30 females (mean age \pm standard deviation [SD], 17 ± 6.3 years). Forty percent of the patients were treated in the first year of life. The median time between initial repair and magnetic resonance imaging

(MRI) was 14 years (range 1.5–24 years). In 45/79 patients (57%), the first surgical repair consisted of resection and end-to-end anastomosis, and in 15 patients (19%) a patch graft aortoplasty. Twelve patients had undergone subclavian flap technique ($n=9$; 11%) or a primary tube interposition graft ($n=3$; 4%). Three patients (4%) were treated interventionally (balloon angioplasty without stent placement) once or twice before their last surgical correction. Two patients had a resection and ascendo-descendo anastomosis (3%), and two others an unknown first procedure (3%).

Ten patients with hypertension were on antihypertensives (4 in monotherapy with a β blocker and 2 with an angiotensin-converting enzyme inhibitor and 4 with a combination of both) and no one with normotension.

The control group consisted of 20 healthy volunteers (18 ± 4.9 years, median 17, range 9–26).

Informed consent was obtained from all participants. Participants less than 18 years of age assented to the participation and their legal representatives consented. The study protocol was approved by the local ethics committee.

Magnetic Resonance Imaging

MRI was performed on 1.5 T whole-body MR systems (Symphony Magnetom [the first 32 patients and the whole control group] and Avanto Magnetom [the last 57 patients], Siemens Medical Solutions, Erlangen, Germany). For signal reception, a standard body-phased array coil was used.

The Examination Protocol

Localization of the aorta (true fast imaging with steady precession) in transversal, coronal, and sagittal orientation.

Two-dimensional (2D) CINE MRI (fast low angle shot [FLASH]) as “bright blood” technique of the aorta in transversal slice orientation, perpendicular angulated to the vessel at the level of diaphragm (**► Fig. 1**) to calculate aortic compliance (C) with following technical details:

- Symphony: TE = 4 ms, TR = 18 ms, FOV 180×180 mm², matrix 192×256 pixel, slice thickness 6 mm, flip angle $\alpha = 40^\circ$.
- Avanto: TE = 3.7 ms, TR = 72 ms, FOV 180×180 mm², matrix 312×384 pixel, slice thickness 3 mm, flip angle $\alpha = 15^\circ$.

The sequence was prospectively electrocardiogram triggered and performed in an inspiratory breath-hold. This sequence was performed in 76 patients at the level of the diaphragm and in 13 at a more proximal level, but not higher than the bifurcation level of the pulmonary arteries (these 13 patients were excluded for the comparison with the volunteers). In these 13 patients, the MR technicians planned the compliance measurement at the wrong anatomical level and the measurements could not be redone.

Two-Dimensional Phase-Contrast Flow Measurements (Pre-, In-, and Poststenoses)

The blood flow velocity measurements were performed with a flow sensitive, phase-contrast (PC) gradient echo pulse

Fig. 1 (A) Sagittal image of the aorta for planning transversal the CINE sequence at the level of the diaphragm (B). (C) Enlarged visualization of the region of interest in the descending aorta with region of interest (ROI) placed for assessment of temporal change of area over time (D).

sequence using the following image parameters: FLASH 2D, echo time/repetition time = 4/9 ms, flip angle 30°, field of view 390 mm, matrix 192 × 256, slice thickness 6 mm, 25 to 39 phases per heart cycle, and high-velocity encoding (VENC) typically of 500 cm/s. The PC-MRI sequences were performed during free breathing. Prior to the quantitative through-plane flow measurements, in-plane flow measurements were performed along the course of the aorta to visualize flow jets and to facilitate positioning of subsequent through-plane measurements. In general, one through-plane PC flow measurement was made in the proximal descending aorta (aortic isthmus, immediately distal to a stenosis). All flow measurements were orientated perpendicular to the main flow jet. If no jet was visible, measurements were orientated perpendicular to the aorta.

For visualization of the aorta, a contrast-enhanced MRI angiography three-dimensional (3D) MR FLASH (TE = 1.8 ms, TR = 4.6 ms, matrix: 215 × 512 pixel, slice thickness 1.25 mm, flip angle $\alpha = 50^\circ$ using 0.2 mmol/kg KG gadolinium-diethylenetriamine pentaacetic acid contrast agent [Magnevist, Schering AG, Berlin, Germany]) were performed in patients.

Compliance

Compliance (C), as a parameter of distensibility, can be assessed with different methods using MRI.^{16,17} In our study, aortic compliance (C) was calculated by assessing aortic distensibility as a relative change in the aortic cross-sectional areas during cardiac systole and diastole, taking into account blood pressure¹⁸:

ΔA = Difference between maximum area (A_{\max}) [m^2] and minimum (A_{\min}) [m^2] of the aorta over the cardiac cycle. ΔP = Blood pressure amplitude (systolic – diastolic blood pressure) [Pa^{-1}].

Finally, these results were calculated in relation to body surface area. All measurements were positioned perpendicular to the descending aorta at the level of the diaphragm (► Fig. 1). Evaluation was done using an in-house developed software (based on IDL version 6.0 Win 32) as previously

described.¹⁷ Contours were placed manually by an experienced observer. The method has already been evaluated for its inter- and intraobserver variability.¹⁷

Velocity Measurements

The analysis of the velocity measurements was performed with a dedicated evaluation software available on the MR scanner (ARGUS) and included the calculation of the mean and peak blood flow velocity and the flow volume. Similar to previous studies, ΔP was estimated from peak velocities measured with MR PC velocity mapping using a simplified or modified Bernoulli equation.^{19–23}

Morphology of the Aortic Arch

The 3D-MR angiography image data sets were postprocessed (maximum intensity projection, multiplanar reconstruction, and volume rendering) (3D tool of Siemens Syngo Workplace). Two observers evaluated the image data in consensus classifying the presence and severity of CoA and the presence of collateral arteries. The grade of CoA was quantified by calculating percent stenosis of perpendicular angulated cross-section area of the stenosis and at a vessel segment distal to the stenosis and near the diaphragm. A significant stenosis was defined as luminal narrowing > 30%.

Assessment of the geometry of the aortic arch was done by putting the width of the aortic arch in relation to the height. The width was defined as the transverse distance between the ascending and descending aorta (center of the vessel) at the level of the pulmonary arteries. The height was determined as the largest distance of the width of the aortic arch to the aortic arch (► Fig. 2). It has to be noted that no patient presented with a hypoplastic arch. As a limitation of the simplified height/width ratio it has to be mentioned that any form of tortuous arch geometry is not acknowledged. However, this aspect is not yet an established feature in patients with coarctation.

Based on previously defined definitions, a height/width ratio of > 0.745 was called gothic, a height/width ratio of ≤ 0.745 was called Romanesque arch.²⁴

Fig. 2 Contrast-enhanced magnetic resonance (MR) angiography of the aortic arch (maximum intensity projection). (A) Romanesque arch. (B) Gothic arch. “B” marks the width as the distance between the ascending and descending aorta (center of the vessel) at the level of the pulmonary arteries. The height “H” was determined as the largest distance of the width of the aortic arch to the aortic arch.

Echocardiography

Echocardiography was performed with a Vivid 7 ultrasound system (GE Healthcare, Chalfont St. Giles, United Kingdom). Parasternal long- and short-axis scanning was performed and was used to measure left ventricular dimensions and aortic annulus size, according to the recommendations of the American Society of Echocardiography.²⁵ Apical and subcostal views were used to assess flow velocity across the aortic valve. Left ventricular systolic function was assessed by measurements of shortening fraction and ejection fraction as index of cardiac function.

Blood Pressure Measurement

Systolic and diastolic blood pressure was measured with Dinamap Pro Care 100 (GE Healthcare) at the right arm and leg before the MRI measurements. Age-related normative data for normal blood pressure in children and adolescents was used, regarding values greater than the 95th percentile as hypertensive (values from measurements of the right arm).²⁶

In patients with an indication for an invasive catheterization, these pressure data were included into the evaluation. No catheterizations were performed within the study protocol.

Statistical Analysis

Analysis was performed using SPSS 15.0 (SPSS Inc. Chicago, Illinois, United States). Results are expressed by mean and range. *t*-Test was performed to compare the aortic compliance between patients and healthy controls, normotensive and hypertensive patients, as well as between different arch types. A *p*-value of ≤ 0.05 was considered to indicate significance unless specified otherwise. Compliance of patients and controls plotted against age were presented as a nonlinear power regression line.

For the correlation of the hemodynamic parameters obtained from MRI with the clinical hemodynamic parameters, a Spearman’s correlation was performed. Differences were tested for significance using a two-sided *t*-test. Significance was assumed with $p \leq 0.05$.

Results

Two-thirds of all patients had an elevated blood pressure (> 90 th percentile). Slightly more than half (54%) showed hypertension (> 95 th percentile), but more than half of them had no significant stenosis (defined as $\geq 30\%$). The compliance was lower in the patients group than in the controls (3.30 ± 2.43 vs. 4.67 ± 2.21 [$10^{-5} \text{ Pa}^{-1} \text{ m}^{-2}$]; $p = 0.024$) (\blacktriangleright **Table 1**).

In both groups compliance is decreasing with increasing patients’ age (\blacktriangleright **Fig. 3**).

The 10 patients on antihypertensives had the lowest values of compliance in comparison to the controls 2.51 to 4.67 ($10^{-5} \text{ Pa}^{-1} \text{ m}^{-2}$) ($p < 0.01$).

Significant differences were found between hyper- and normotensive patients (2.61 ± 1.60 vs. 4.11 ± 2.95 ; $p = 0.01$). No difference was found between normotensive patients and controls (\blacktriangleright **Fig. 4**, \blacktriangleright **Table 2**).

Following a regression analysis, the compliance was found to be a highly significant predictor for the systolic blood pressure and the presence of hypertonia ($p < 0.01$ for the

systolic blood pressure group and $p=0.032$ for the blood pressure group).

Compliance and Aortic Arch Geometry

The control group showed a Romanesque arch.

The patients were divided into two groups of varying aortic arch geometry. The patients with gothic arches showed a lower compliance than patients with Romanesque arches (2.64 ± 1.58 vs. 3.78 ± 2.81 [10⁻⁵ Pa⁻¹ m⁻²]; $p=0.027$). Also, a significant difference was found between the patients with gothic arches and the controls ($p<0.01$). The difference between patients with Romanesque arches and controls was not significant ($p=0.213$) (►Table 3, ►Fig. 5).

Correlation of Compliance to Blood Pressure, Degree of Stenosis, Pressure Gradient, Type of Repair, and Timing

The blood pressure of the patients was (mean) 132/67 mm Hg (SD ± 20/11 mm Hg) assessed at the upper extremity and 129/66 mm Hg (SD ± 23/10 mm Hg) at the lower extremity. A good correlation between systolic and diastolic blood pressure as

Table 3 Comparison between patients with different architecture of the aortic arch (patients included with compliance measurements at the level of the diaphragm, *n* = 76) with controls

	"Romanesque" Height/Width ≤ 0.745	"Gothic" Height/Width > 0.745	Controls

Abbreviations: BSA, body surface area; SD, standard deviation.

well as blood pressure percentile and the compliance were found (► **Table 4**).

Only 14 patients had a systolic pressure gradient of ≥20 mm Hg between the upper and lower extremity indicating a significant stenosis. Eight of those had a stenosis of > 30%.

There was no correlation between the compliance and the pressure gradient (by echocardiography/Doppler, heart catheter/invasive pressure measurements, or MRI/flow measurements). The degree of stenosis showed no correlation with the systolic blood pressure (*p* = 0.8) or the blood pressure percentile (*p* = 0.145).

Based on the MRI measurements (degree of stenosis [%] = smallest diameter within the arch/diameter at the level of the diaphragm), 35 patients (39%) showed a significant stenosis (> 30%), 4 of those even a stenosis > 60%. Fifty-four patients (61%) showed a nonrelevant stenosis, of those 20 patients had a stenosis > 10%. Twenty-seven patients (30%) suffered from hypertension (≥90 blood pressure percentile) and had a significant stenosis. Eight patients (9%) had a stenosis but no hypertension, and 18 patients (20%) no

Table 4 Correlation between the compliance and blood pressure

	Systolic blood pressure	Diastolic blood pressure	Systolic blood pressure percentiles
Ratio of correlation coefficient to compliance	0.671	0.299	0.445
Level of significance, <i>p</i>	< 0.01	< 0.01	< 0.01

hypertension and no stenosis. Thirty-six patients had hypertension without stenosis.

The degree of stenosis showed no correlation with the compliance (*p* = 0.965). The 35 patients with significant stenosis showed a reduced compliance compared with the control group (3.58 vs. 4.67 [10^{−5} Pa^{−1} m^{−2}]), without reaching significance. Forty percent of patients with significant stenosis (14 of 35 patients) showed a normal compliance (≥5th percentile) (► **Fig. 6**).

Timing of Surgery

Twenty-five patients were operated within the first year of life (33%, based on 76 patients with a compliance measurement). Seven patients (9%) were operated in their second year of life, 7 patients (9%) in their third year, 4 (5%) forth year, 8 (11%) fifth year, and 14 (18%) after the fifth year. The latest surgical procedure was performed at the age of 19. In 11 patients, the time of surgical repair could not be identified.

There was no impact of the timing of the first surgical procedure on the compliance of the aorta. In 39% of the patients, MRI showed a significant restenosis (≥30%). Patients who were operated within their first year of life showed in 5 out of 25 cases a significant restenosis (20%). Patients who were operated later in life showed in 24 out of 51 cases a significant restenosis (47%).

Eighteen out of 25 patients (72%) who were operated within their first year of life suffered from hypertension (> 90th percentile). Patients who were operated later in life (36 out of 51 patients, 71%) showed a similar rate of hypertension.

Fig. 5 Boxplot diagram showing the compliance/body surface area (BSA) with different configurations of the aortic arch and the controls (*p* = 0.213, Romanesque arch vs. controls).

Fig. 6 Compliance/body surface area (BSA) only of patients with significant stenosis and the control group. As reference lines are the 95th and 5th percentile of the compliance of the control group as exponential regression provided.

Influence of Type of Surgical Repair to Compliance

Surgically corrected patients showed a reduced compliance compared with the controls ($3.07\text{--}4.67 [10^{-5} \text{ Pa}^{-1} \text{ m}^{-2}]$, $p < 0.01$). The type of surgical repair had no influence on the compliance or number of restenosis. However, differences between the blood pressure were found. Native CoA patients showed similar compliance values than the controls ($5.02\text{--}4.67 [10^{-5} \text{ Pa}^{-1} \text{ m}^{-2}]$).

Patients operated with tube interposition graft, subclavian flap technique, and corrected with unknown technique showed hypertension while the others were normotensive (→ **Table 5**).

There was a good correlation between compliance and hypertension ($r = 0.671$; $p < 0.01$), but no correlation between compliance (and hypertension) and time or kind of repair, restenosis, or pressure gradients.

Table 5 Influence of the type of surgical repair on blood pressure, degree of stenosis, and compliance

	Number [n]	Mean blood pressure percentile	Mean degree of stenosis [in %]	Compliance/BSA mean \pm SD [$10^{-5} \text{ Pa}^{-1} \text{ m}^{-2}$]
Tube interposition graft	2	98.5 ± 0.71	20 ± 9.9	2.28 ± 0.81
Subclavian flap	9	94.7 ± 4.3	23.1 ± 20.3	2.28 ± 0.71
Other/unknown	2	94.0 ± 1.4	12.5 ± 14.5	4.41 ± 2.98
Native CoA	9	71.9 ± 23.9	32 ± 14.9	5.02 ± 5.08
End-to-end anastomosis	40	88.9 ± 16.0	27.1 ± 19.2	3.32 ± 1.89
Patch graft aortoplasty	12	88.6 ± 16.5	23.9 ± 22.5	2.34 ± 0.88
Ascendo/ descendostomy	2	70 ± 14.1	12.0 ± 17.0	5.47 ± 3.37

Abbreviations: BSA, body surface area; CoA, aortic coarctation; SD, standard deviation.

Table 6 Multivariate analysis with type of aortic arch as constant variable

Variable	Coefficient	t	p-Value
Type of repair	-0.027	-0.308	0.759
Age at repair	-0.028	-0.243	0.809
Systolic blood pressure	-0.200	-0.989	0.326
Systolic blood pressure percentile	0.244	1.330	0.188
Compliance	0.054	0.489	0.627

Using a multivariate analysis the influence of type of repair, age at time of repair, systolic blood pressure, blood pressure percentile, or compliance of the geometry of the aortic arch was assessed. No parameter reached significance (► **Table 6**).

Discussion

Hypertension is one of the leading cardiovascular issues in patients with treated CoA.²⁷ It is well acknowledged that hypertension has a multifactorial origin. An increased arterial stiffness is discussed as one of the main drivers; however, even the latest review article focuses only on the prestenotic/ascending aorta.^{27,28} Also, various other aspects like type of surgical repair or timing or aortic arch geometry are discussed.

In this field, still under investigation, our large population study adds some major insights. Using MRI the compliance of the aorta was assessed for the first time (to our knowledge) at the level of the diaphragm and therefore far away from the isthmus and also not in the prestenotic region and compared with healthy controls.

The technique used in our study for measuring compliance can be performed using any MR machine without special sequences or postprocessing tools.

As mentioned above, this technique was evaluated previously and found valid results.^{16–18} The change of area and blood pressure have influence on the compliance. We also assessed the influence of systolic pressure, diastolic pressure, and difference between systolic and diastolic pressure, at right arm and right leg. We could not find a significant correlation between these parameters and the compliance by themselves, therefore we used in all patients and subjects the blood pressure which was measured at the right arm. Still, there might be the possibility that a “delta” P could be driven by a high systole alone in single cases but not in all patients. In the majority of the hypertension group, systolic and also diastolic pressure increased in a similar way without any change of “delta” P.

There are newer techniques available like four-dimensional flow measurements or computational fluid dynamics simulations, even allowing for assessment of wall shear stress, but these techniques require much more acquisition time and dedicated postprocessing tools, not yet broadly available.²⁹ Other possibilities include simulation of wall shear stress using computational fluid dynamics.³⁰ Especially, these techniques are highly experimental and not broadly available.

Our population showed a manifest hypertension in 54% of cases, which is in the expected range for this patient collective.³¹ The presence of arterial hypertension correlated with a significantly decreased compliance of the aorta at the level of the diaphragm. This finding did not correlate with any other parameter like type or timing of surgical repair or degree of restenosis. This supports the hypothesis of a global systemic vascular disease.^{30,32,33} Our findings are in contradiction to a previous study showing a reduced compliance of the ascending aorta was found and no change in compliance in a poststenotic segment.²⁴ In this previous study, normotensive patients were examined and the poststenotic measurement was in the area potentially affected by surgery (scar tissue or poststenotic aortic dilatation). In our study, measurements were performed at the level of the diaphragm, remote of the location of surgery.

We confirmed the finding, that hypertension has no correlation with the degree of restenosis.^{14,34}

On the other hand, 40% of patients with a significant restenosis ($\geq 30\%$) showed a normal compliance of the aorta. This underlines the individual aspect of the elastic properties of the aorta within the disease group of coarctation patients.

Timing of surgery had an influence on the risk of developing a restenosis, as previously suggested a younger age at the time of surgery (< 1.5 years) has a significantly reduced risk of development of a restenosis.⁶ However, in our collective, the timing of surgery had no influence on development of hypertension which is in keeping with previous reports.^{2,5,14,33}

There was no correlation between degree of restenosis and systemic blood pressure or the pressure percentile. Half of all patients with hypertension had no significant stenosis. Nearly one-half of all patients had hypertension without stenosis. Conversely, 40% of patients with significant stenosis showed a normal compliance (≥ 5 th percentile).

Interestingly, the type of surgical repair had a significant influence on the development of hypertension. Previously, subclavian flap repair showed worse outcome than end-to-end anastomosis.³⁵ In our population, also patients treated with a tube interposition graft showed hypertension. However, the type of surgical repair had no influence regarding the compliance or degree of restenosis.

A gothic arch geometry is a common finding in patients with coarctation.³⁶

Regarding the influence of the arch geometry onto hypertension and compliance, mainly the ascending aorta was studied so far and a decreased compliance and increased arterial wave reflection was found for a gothic arch configuration.^{27,37} In a previous study, it was postulated, that a gothic arch configuration results in an increased reflection of the aortic wave with subsequent increased left ventricular hypertrophy and increased systolic pressure.²⁴ In a more recent study, no relationship between a gothic arch configuration and coarctation index or central aortic systolic blood pressure was found.²⁸ In our study, we found a significant lower compliance also at the level of the diaphragm in patients with a gothic arch configuration. Therefore, those patients seem to have a globally changed compliance of the aortic wall and hypertension is a subsequent result. This would also explain the differences

between those patients with a Romanesque arch and controls—there was a nonsignificant difference in the aortic compliance. This is in keeping with another study in patients without congenital heart disease.³⁸ Similarly, this might account for patients with coarctation not yet suffering from hypertension but already showing a reduced compliance.^{39,40}

As limitations of our study, it has to be mentioned, that our patient population was quite inhomogeneous, that is, regarding type of surgical repair. This is a frequently seen issue in longitudinal studies in patients with congenital heart diseases. However, this heterogeneity allowed us to compare the whole bandwidth, that is, types of surgical repair and the respective outcome. That two different MRI scanner were used, is less of an issue as the temporal and spatial resolution for assessment of compliance was sufficient, as a large vessel (descending aorta) was evaluated.

Assessment of the aorta was done using a contrast-enhanced angiography. Recently, it was shown that MR contrast media are deposited in the brain and thus the use of MR contrast should be handled restrictively. For visualization of the aorta, dark blood sequences and submillimetric T2-weighted images should be used.

In conclusion, we could show that at least the majority of patients with coarctation do suffer from a primary systemic vessel disease with generally reduced compliance. This seems to be a major driver for development of arterial hypertension. For patient management, it can be concluded that patients with a normal compliance might benefit from retreatment (operation and/or intervention) in case of a restenosis. Also, patients with reduced vascular compliance and no hypertension should be identified for closer blood pressure monitoring.

Funding

This work was supported by “Forschungsförderung der Medizinischen Fakultät” of the University of Heidelberg (project No.: 222–2002).
