Abstract

Introduction Parkinson disease (PD) is a progressive degeneration characterized by motor disorders, such as tremor, bradykinesia, stiffness and postural instability.

Objective To evaluate the independence, confidence and balance in the development of daily activities in patients with PD before and after rehabilitation.

Methods A descriptive, retrospective cross-sectional study was carried out with 16 patients (mean 57.6 ± 18.7 years), submitted to anamnesis, otolaryngological evaluation and vestibular assessment. The Vestibular Disorders Activities of Daily Living (VADL) and the Activities-Specific Balance Confidence (ABC) scales were applied before and after rehabilitation with virtual reality.

Results a) The *instrumental* subscale of the questionnaire showed statistically significant result ($p = 0.022$; 95% CI 1.21; 2.21) between the first and second assessments; b) The correlation between the questionnaires showed statistically significant result in the *ambulation* subscale ($p = 0.011$; 95% CI -0.85 ; -0.17) first and ($p = 0.002$, 95% CI -0.88 ; -0.31) second assessments, and the *functional* subscale was only verified in the second assessment ($p = 0.011$, 95% CI -0.85 ; -0.17); and c) The patients presented clinical improvement in the final assessment after rehabilitation with significant result for the *tightrope walk* ($p = 0.034$, 95% CI -12.5 ; -0.3) and *ski slalom* games ($p = 0.005$, 95% CI -34.8 ; -6.6).

Conclusions Our results showed that the VADL and ABC questionnaires, applied before and after rehabilitation, were important tools to measure the independence, confidence and balance while developing daily activities. The VADL and ABC questionnaires may effectively contribute to quantify the effect of the applied therapeutics and, consequently, its impact on the quality of life of patients with PD.

Introduction

Parkinson disease (PD) is a chronic disorder with progressive degeneration of the dopamine-producing cells in brain structures, including the substantia nigra. Its major symptoms are motor disorders, such as tremor, bradykinesia, stiffness and postural instability,^{1,2} causing functional decline, impairing the performance of activities of daily living (ADLs) and resulting in the reduction of physical independence and quality of life (QOL).³ Patients with PD have difficulties performing ADLs, specially tasks demanding coordination and balance.^{4,5}

The elderly population, who have the greatest incidence of PD, present impaired balance. Postural instability occurs as the disease progresses, thus causing functional independence and, consequently, increasing the risk of falls.^{6,7} Although falls significantly affect the ADLs and the QOL of patients with PD, the underlying neural mechanisms associated with frequent falls in PD patients are still unclear.⁷

Vestibular rehabilitation (VR) aims to modify the postural control system by means of specific, repetitive physical exercises under different conditions. It has been shown to act physiologically upon the vestibular system, being considered a therapeutic resource due to its performance proposal, based on the central mechanisms of neuroplasticity.⁸ The central nervous system (CNS) processes the information and responds to it by means of reflexes, the vestibulo-ocular reflex (VOR), which allows visual stabilization during the head movements, and the vestibulospinal reflex (VSR), which generates a body compensation movement in order to keep head and body stability, thus preventing falls. Neuroplasticity refers to the capacity of the CNS to modify some of its morphological and functional properties as a response to environmental changes.⁸

Imbalance and fear of falls may hinder the performance of ADLs, especially activities demanding fast head motions, and trunk and/or head flexions.⁹ Difficulties in carrying out ADLs can be assessed by means of formerly validated questionnaires. Among the existing instruments, we point out the Vestibular Disorders Activities of Daily Living (VADL) and the Activities-Specific Balance Confidence (ABC) scales.

Thus, the objective of the current study was to evaluate the independence, confidence and balance in the development of daily activities in patients with PD before and after rehabilitation.

Methods

Participants and Study Design

This study was approved by the Research Ethics Committee (Plataforma Brasil)—opinion number 832.502/2014, and authorized by the patients, who signed the Free Informed Consent Form. The study follows the principles of the Declaration of Helsinki.

A descriptive, retrospective cross-sectional study was carried out. The sample included 16 patients (6 female and 10 male) with PD who were referred by the department of neurology from the clinical hospital for assessment in the

department of otoneurology of a teaching institution in the same city. The diagnosis of PD was held according to the Queen Square Brain Bank criteria. The mean age of the patients was between 18 and 82 years (mean 57.5 ± 18.7 years). The mean disease duration was 5.1 ± 3.2 (1 year, and 11 years maximum).

Adult patients with PD, not diagnosed with middle-ear disorders, no use of walking devices, and not formerly submitted to any rehabilitation therapy were included in the study. Patients with ear disorders, incapable of complying with and understanding simple verbal commands, and visually impaired were excluded.

All patients underwent otorhinolaryngological assessment, anamnesis and vestibular system screening with digital vector electronystagmography (VENG), which has its own software VecWin2 (Neurograff Eletromedicina LTDA, São Paulo, SP, Brazil), a rotating chair model COD 14200, rotation 0.01 to 0.5Hz, (Cadeiras Ferrante Ltda, São Paulo, SP, Brazil), a visual stimulator model EV VEC (Neurograff Eletromedicina LTDA, São Paulo, SP, Brazil), and an air caloric stimulator model NGR 05 (Neurograff Eletromedicina LTDA, São Paulo, SP, Brazil). The flow rate used was 5 and 13 L/min.

Subsequently, the VADL¹⁰ and the ABC¹¹ questionnaires were applied. They were applied before rehabilitation (1st assessment) and after the 20th session of rehabilitation (2nd assessment), aiming at observing the prospective post-intervention changes.

Vestibular Disorders Activities of Daily Living Scale (VADL) – culturally adapted to the Brazilian population by Aratani et al,¹⁰ it assesses the dependence and the impact of body imbalance on the performance of daily activities. The questionnaire includes 28 daily living activities divided into three subscales, functional (12 activities), ambulation (9 activities), and instrumental (7 activities). Using a qualitative scale, the patients are assigned 0 to 10 points according to their performance and independence in performing each described activity. The score is calculated from the median of values, in which the higher the score the higher the dependence and inability of the patient. For “Not Applicable” (N/A) answers, that is, the patient does not perform the activity or does not want to reply, the question is given zero points.

Activities-specific Balance Confidence Scale (ABC) – culturally adapted to the Brazilian population by Marques et al,¹¹ it assesses the level of confidence of the individual in the ability to maintain balance while performing specific daily activities. The questionnaire comprises 16 questions on how confident subjects are to carry out a certain activity (not confident = 0%, and completely confident to carry out the activity without losing balance = 100%). Therefore, the higher the percentage, the greater their self-confidence.

Vestibular Rehabilitation with Virtual Reality (VR)

The exercises aim to improve the vestibulo-visual interaction during head movements, to increase static and dynamic postural stability under conditions that produce conflicting sensory information, to improve the ability in performing daily activities, and to provide patients with greater physical independence.⁸

Vestibular rehabilitation with VR is a therapeutic method used in body-balance rehabilitation. Nintendo Wii equipment, Wii remote e Wii balance Board (Nintendo Co, Ltd., Kyoto, Japan) were used. This platform measures the applied strength, and records slight balance changes by means of pressure sensors. At first, patients got familiar with the game and were instructed regarding the necessary movements to play it. The Wii balance board entails reactive and proactive strategies of postural control by means of visual feedback as well as the challenge for better performance in order to finish the games.

Four balance games were carried out (soccer heading, table tilt, tightrope walk e ski slalom) with strategies involving saccadic, optokinetic stimuli, head movement, static and dynamic balance, motor coordination, eye-pedal coordination, circular pelvis movements, knee flexion-extension, ankle-hip movements, back to front and side to side movements and weight transfer, aiming at balance disorders and postural instability.

All patients carried out 20 VR sessions individually, 50 minutes each (10 minutes of heating exercises and 40 minutes of balance exercises), twice a week, and were submitted to the same assessing questionnaires before and after the end of the rehabilitation sessions. The patients performed this type of intervention exclusively with games and were not oriented to perform any type of complementary traditional exercise at home.

Statistical Analysis

Data analyses were held by means of descriptive statistics, Friedman analysis of variance (ANOVA), Spearman Correlation Coefficient and paired Student *t*-test at a significance level of 0.05 [(5%) by means of the Statistica 13.1 software

Table 1 Symptoms in patients with Parkinson disease (n = 16)

| SYMPTOMS | n | % |
|-------------------------|----|------|
| Tremor | 12 | 75.0 |
| Muscle stiffness | 12 | 75.0 |
| Imbalance | 10 | 62.5 |

| Tiredness when speaking | 1 | 6.2 |

Abbreviation: n, number; PD, Parkinson disease.

(StatSoft, Inc., Tulsa, OK, USA). For the tests, the 95% confidence interval (CI) was applied.

Results

The most reported complaints during the anamnesis were: tremor and muscle stiffness (75% each), imbalance (62.5%), difficulty in gait and dizziness (43.7% each), as shown in **table 1**.

Disorders in the vestibular testing were evidenced in 5 cases (31.2%), with 3 cases (18.7%) of peripheral vestibular deficit dysfunction and 2 cases (12.5%) of hyperreflexia/vestibular dysfunction. Testing results were normal in 11 cases (68.8%). Results of the VADL questionnaire can be observed in **table 2**.

Table 3 Results of the Activities-Specific Balance Confidence questionnaire (n = 16)

| ASSESSMENT | DESCRIPTIVE STATISTICS | | | | | P | 95% CI |
|----------------|------------------------|--------|-------|--------|-------|-------|----------------|
| | MEAN | MEDIAN | MIN | MAX | SD | | |
| 1st assessment | 74.79 | 80.94 | 27.50 | 100.00 | 20.59 | 0.459 | −18.27; −10.35 |
| 2nd assessment | 78.75 | 89.38 | 31.25 | 97.50 | 19.05 | | |

Abbreviations: ABC, Activities-Specific Balance Confidence; CI, confidence interval; Min, minimum; Max, maximum; SD, standard deviation.

*Friedman analysis of variance (ANOVA) test.

The application of the Friedman ANOVA test showed no statistically significant difference for the subscales: Functional ($p = 0.240$, 95% CI from -0.43 – 0.81) and ambulation ($p = 0.225$, 95% CI from -0.71 – 0.73). The instrumental subscale evidenced statistically significant difference ($p = 0.022$, 95% CI from 1.21 – 2.21) between the 1st and 2nd assessments. For the general assessment, there was also no significant difference ($p = 0.054$, 95% CI from -0.36 – 1.30). The results of the ABC questionnaire are shown in **Table 3**.

The application of the Friedman ANOVA test showed no significant difference between the scoring of both assessments ($p = 0.459$, 95% CI from -18.27 to -10.35).

The correlation result between the VADL and ABC questionnaires can be seen in **table 4**.

The application of the Spearman correlation coefficient evidenced significant correlation ($p = 0.011$, 95% CI from -0.85 to -0.17) ($p = 0.002$, 95% CI from -0.88 to -0.31) between the VADL and ABC questionnaires for the ambulation subscale in both assessments, while for the functional subscale, correlation was only verified in the 2nd assessment ($p = 0.011$, 95% CI from -0.85 to -0.17). For the instrumental subscale, there was no significant correlation in any assessments. For the general assessment, there was a statistically significant correlation ($p = 0.010$, 95% CI from -0.85 to -0.18) in the 1st assessment. As the correlation coefficient always resulted negative, it was evidenced an inverse correlation between the questionnaires, that is, the lowest scores in the VADL questionnaire correspond to the highest scores in the ABC questionnaire, thus evidencing that the best results in the VADL questionnaire correspond to the best results in

the ABC questionnaire. As for the subscales, the highest correlations occurred in the ambulatory subscale.

The correlation between age and disease duration according to the VADL and ABC questionnaires can be observed in **table 5**.

The application of the Spearman correlation coefficient revealed no significant correlation between disease duration according to the VADL and ABC questionnaires in any assessments.

The result of virtual games (1st assessment) and (2st assessment) is shown in **table 6**.

The Student *t*-test evidenced a statistically significant difference between the tightrope walk ($p = 0.034$, 95% CI from -12.5 to -0.3) and the ski slalom ($p = 0.005$, 95% CI from -34.8 to -6.6) games, showing that these games were more efficient for this type of population than the other games used along the therapeutic intervention. Patients reported that the improvement was reflected in their daily activities.

Discussion

Gait and balance impairments are common symptoms of PD. Such motor symptoms are debilitating, leading to the decline of the patients in their self-perception and balance confidence.^{12–14} The reduction in the ability to walk, as well as the postural instability have been identified as causes for the fear of falling and reduced mobility, with consequent reduction in the QOL of subjects with PD. Studies^{3,15,16} observed gait difficulty in 83% of individuals, expressed

* r_s test.

by slowness and shortening of steps, difficulty in beginning the gait and balance deficit. Authors stated that those disabilities occur due to improper functioning of the basal ganglia to perform muscle adjustments during locomotion, thus leading to freezing episodes and increase in the double-support phase, that is, the period of greater gait stability. Knowingly, motor symptoms precede disability; therefore, physical aspects are pivotal for worsening the QOL of subjects suffering from PD. These results are consistent with our findings.

Mhatre et al² claim that impairments in balance and postural stability contribute to increase the risk of falls and fractures in this population. Falls are a major health problem among the elderly population. The brain needs to process signals from the visual, vestibular and somatosensory systems to maintain postural stability.^{17,18} The combined loss of sensory signals has been pointed as a major cause of imbalance.¹⁸ As a consequence, the elderly population develops the fear of falls, reduces their self-confidence to carry out ADLs, and end up adopting a less active lifestyle.¹⁹

The tests that make up the vestibular exam allow us to evaluate the relationship between balance and posterior labyrinth function, vestibular branches of the VIII cranial nerve, vestibular nuclei of the floor of the fourth ventricle,

vestibular pathways and, above all, the vestibulo-oculomotor, vestibulocerebellar, vestibulo-spinal and cervico-vestibular proprioception interrelationships. The authors^{20,21} point to the prevalence of peripheral vestibular alterations in the elderly. The authors²² evaluated 30 Parkinsonian patients and reported 25 abnormal exams (23 cases with peripheral vestibular alterations and two cases with central vestibular alterations) and 5 cases within the normal limits. The fact that we do not observe a relevant number of central vestibular alterations in PD is due to the disease stage of the patients.

Concerning the application of the VADL questionnaire was statistically significant ($p < 0.05$) was observed for the instrumental subscale. Patients with PD have greater risk to reduce their ADLs with the progression of the disease, particularly activities demanding coordination, balance and mobility,^{23,24} thus causing them dependence and the consequent negative impact on their QOL.^{25,26} The concept of QOL is highly complex and refers to the perception of the subjects regarding their disease and its effect on their lives, involving personal satisfaction associated with their physical, functional, emotional and social well-being. In the context of chronic diseases, the maintenance of QOL must be one of the treatment concerns.¹³

*Student t -test.

The correlation between the ABC and VADL questionnaires was statistically significant ($p < 0.05$) in both assessments for the ambulation subscale, which assesses the perception of mobility-related abilities, while for the functional subscale, which assesses the individual perception of basic self-maintenance activities, significance was evidenced in the 2nd assessment. In the general assessment, there was significant correlation in the 1st assessment. Corroborating our findings, Cohen⁹ reported that imbalance may hinder the performance of daily activities, such as those that demand fast head motion, as well as tasks demanding trunk and head flexion.

The authors²⁷ assessed 104 subjects with idiopathic PD (averaging 66.5 years old, disease duration of 8.8 years) and observed that there was strong correlation to turning and gait measures related to rhythm and dynamic stability during the gait in the ABC questionnaire. In addition, there were poor correlations between the ABC questionnaire and postural sway in an upright, standing position. The study evidenced coherence in the correlation patterns (that is, the severity of the disease as well as patients' perception of their mobility impairment were related to the same objective mobility measures). Corroborating our findings, Bryant et al¹⁶ reported striking differences in the walking speed, stride length during backward and forward gait and 360 degree turn among individuals with PD who feared falls. The study provided better understanding for the relation between balance and gait measures and patients perceived impaired mobility. Detailed understanding on how neurological disorders cause balance and gait dysfunction, which affect patients' lives and are related to the disease severity, will be helpful to orient rehabilitation interventions, that is, improvement in the turning speed, gait speed and stride length. The authors⁵ report that a wide range of subjective and objective assessments have been used to assess balance in subjects with PD. However, little is known on the relation between self-perception and balance confidence. Authors¹⁵ applied the ABC questionnaire to 44 individuals after the performance of static and dynamic balance tasks. The center of pressure and the center of mass were calculated and the severity of the disease was observed to influence confidence relations and control of the static and dynamic balance.

Regarding the exergames used, we observed, with the application of the VADL and ABC questionnaires before and after 20 rehabilitation sessions, the improvement in the independence, confidence, and balance with tightrope walk and ski slalom games, showing that such games were more efficient for this type of population than the other games played. Canning et al²⁸ carried out exercises with 231 subjects suffering from PD for 6 months, 3 times a week, 40 to 60 minutes each session, and reported that lower-limb balance and strength exercises may not only improve balance and gait but also enhance the confidence and QOL of the patients. Zettergren et al²⁹ observed Nintendo WiiFit-related benefits. These benefits include an increase in patients' adherence to the exercises, improvement in the social interaction and self-esteem. The authors³⁰ analyzed the use of dancing for balance and mobility training, and found im-

provement in balance and mobility in 20 sessions for 10/13 weeks. In animal trials, Petzinger et al³¹ showed that exercising may alter dopaminergic neurotransmission. Studies³² have pointed that patients' participation in training programs has proved efficient to reduce depression, falls, fatigue, thus improving their QOL. By applying the ABC questionnaire before and after the training, Mhatre et al² and Acarer et al³³ reported that patients with PD evidenced stiffness reduction, balance improvement, reduction in the postural sway and better QOL, corroborating our findings.

The authors of the present study suggest for future studies the inclusion of Vestibular Evoked Myogenic Potential (VEMP), which, associated with functional tests, may improve/complement the findings of subjective tests.

Conclusion

Our results showed that the VADL and ABC questionnaires, applied before and after the rehabilitation training, were major tools to measure independence, confidence, and balance in the development of daily activities.

The VADL and ABC questionnaires may effectively contribute to quantify the effect of the applied therapeutics and, consequently, its impact on the QOL of patients with PD.

Funding

This work was supported by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brazil (CAPES) under grant number 001.

Conflict of Interests

The authors have no conflict of interests to declare.

The authors M. I. R. S. and G. J. B. S. performed data collection, tabulation, and literature review; J. M. M. performed statistical analysis and literature review; H. A. G. T., J. S. M., M. R. J., M. R. R., P. B. N. L. and R. S. S. performed manuscript writing and final revision; and B. S. Z. was responsible for the project and study design in addition to general supervision of the performance steps and manuscript elaboration.
