Reducing Radiation Dose in Adult Head CT using Iterative Reconstruction – A Clinical Study in 177 Patients

Dosisreduktion bei der cranialen CT mit Hilfe iterativer Rekonstruktion – eine klinische Studie an 177 Patienten

- filtered back projection

Zusammenfassung

Ziel: Es war das Ziel dieser Studie zu untersuchen, inwiefern die adaptive statistische iterative Rekonstruktion (ASIR) zur Dosisreduktion bei der cranialen Computertomografie (cCT) beiträgt und welchen Einfluss sie auf die Bildqualität hat.

Material und Methoden: Es wurden 177 native cCT unter Notfallbedingungen durchgeführt. Insgesamt wurden 4 verschiedene Protokolle genutzt: Gruppe A (Kontrollgruppe): 120 kV, FBP (filtered back projection) n = 71; Gruppe B1: 120 kV, Scan und Rekonstruktion durchgeführt mit 20 % ASIR (Überblendung von 20 % ASIR und 80 % FBP), n = 86; Gruppe B2: Rohdaten aus Gruppe B1 wurden mit einer Überblendung von 40 % ASIR und 60 % FBP rekonstruiert, n = 74; Gruppe C1: 120 kV, Scan und Rekonstruktion durchgeführt mit 30 % ASIR, n = 20; Gruppe C2: Rohdaten aus Gruppe C1 wurden mit einer Überblendung von 50 % ASIR und 50 % FBP rekonstruiert, n = 20. Die Effektivdosis aller CTs wurde berechnet; die Bildqualität wurde sowohl quantitativ als auch qualitativ evaluiert.

Abstract

Purpose: To assess how ASIR (adaptive statistical iterative reconstruction) contributes to dose reduction and affects image quality of non-contrast cranial computed tomography (cCT).

Materials and Methods: Non-contrast emergency CT scans of the head acquired in 177 patients were evaluated. The scans were acquired and processed using four different protocols: Group A (control): 120 kV, FBP (filtered back projection) n = 71; group B1: 120 kV, scan and reconstruction performed with 20 % ASIR (blending of 20 % ASIR and 80 % FBP), n = 86; group B2: raw data from group B1 reconstructed using a blending of 40 % ASIR and 60 % FBP, n = 74; group C1: 120 kV, scan and reconstruction performed with 30 % ASIR, n = 20; group C2: raw data from group C1 reconstructed using a blending of 50 % ASIR and 50 % FBP, n = 20. The effective dose was calculated. Image quality was assessed quantitatively and qualitatively.

Results: Compared to group A, groups B1/2 and C1/2 showed a significantly reduced effective dose of 40.4 % and 73.3 % (p < 0.0001), respectively. Group B1 and group C1/2 also showed significantly reduced quantitative and qualitative image quality parameters. In group B2, quantitative measures were comparable to group A, and qualitative scores were lower compared to group A but higher compared to group B1. Diagnostic confidence grading showed groups B1/2 to be adequate for everyday clinical practice. Group C2 was considered acceptable for follow-up imaging of severe acute events such as bleeding or subacute stroke.

Conclusion: Use of ASIR makes it possible to reduce radiation significantly while maintaining adequate image quality in non-contrast head CT, which may be particularly useful for younger patients in an emergency setting and in follow-up.

Kernaussagen:
- Durch ASIR kann die Dosisexposition bei klinisch adäquater Bildqualität signifikant vermindert werden
- 20 % ASIR cCT mit 40 %ASIR/60 %FBP Überblendung sind ausreichend für täglichen klinischen Gebrauch
- 30 % ASIR cCTs mit 50 %ASIR/50 %FBP Überblendung sind ausreichend für Folgebildgebungen

Key Points:
- ASIR may reduce radiation significantly while maintaining adequate image quality
- cCT protocol with 20 % ASIR and 40 %ASIR/60 %FBP blending is adequate for everyday clinical use
- cCT protocol with 30 % ASIR and 50 %ASIR/50 %FBP blending is adequate for follow-up imaging

Citation Format:

Introduction

The use of computed tomography (CT) has been constantly increasing over the last decades and leads to higher cumulative doses of ionizing radiation in the population [1]. According to a recent survey conducted by the German Agency for Radiation Protection, CT examinations constitute 8 % of all radiological examinations and account for 63 % of the total population dose due to radiological examinations [2].

With the widespread availability of CT scanners, emergency departments have seen a remarkable increase in the use of cranial CT (cCT). In an emergency setting, non-contrast cCT is usually performed to rapidly rule out intracranial pathology. However, many patients who undergo emergency cCT have no intracranial pathology at all. Furthermore, there is growing evidence that the increasing use of cCT in younger patients will lead to a higher rate of brain cancer in the future [3].

One of the principles of modern radiology is to apply the lowest possible amount of ionizing radiation while maintaining diagnostic image quality. Efforts made to reduce overall radiation exposure have led to new technologies, such as automated tube current modulation and noise reduction filters [4, 5]. Unfortunately, dose reduction with both techniques is limited when a head with a thick skull bone is examined [6]. Lowering the tube potential in the acquisition of cCT scans reduces radiation effectively but comes at the cost of increased image noise [7].

With the recent developments in computing power, iterative reconstruction (IR) algorithms, which were first introduced for single-photon emission computed tomography (SPECT) and positron emission tomography (PET), can now also be applied to CT [8, 9]. IR algorithms eliminate some of the increased image noise resulting from the use of a lower tube current for the acquisition of CT scans.

Pilot studies have shown that IR algorithms have the potential to reduce the radiation dose of cranial CT scans by 20 – 45 % [10 – 13].

This clinical study analyzes the effect of IR on effective radiation doses, image quality and interpretability in comparison with routine CT scans of the head based on filtered back projection (FBP) in a large patient population examined in an emergency setting.

Materials and Methods

Study Design

The institutional ethics board approved this study. Since patients were not exposed to additional radiation and their data were stored anonymously, the informed consent requirement was waived. Five protocols – A, B1, B2, C1 and C2 – with increasing dose reduction potential were used.

Patients in group A and group B1/B2 were referred from the first-aid department. Patients in group C1/2 had undergone head CT before and were referred by the neurosurgical intensive care unit (ICU) for follow-up CT. We did not use protocol C1/2 (protocol with highest dose reduction potential) on first-aid patients to avoid the risk of having to repeat the CT examination due to insufficient image quality.

Most patients underwent cCT for one of the following acute events: trauma and/or amnesia, skull fracture, loss of consciousness, seizure, headache, vomiting, focal neurological deficit, coagulopathy, treatment with anticoagulants, increasing frequency of unexplained headaches or new onset of severe or persistent headache.

Intracranial foreign material was considered an exclusion criterion in groups A, B1 and B2 but not in group C1/2, since virtually all neurosurgical ICU patients carry intracranial foreign material.

CT Protocol

Protocols are summarized in Table 1. All patients were examined on a 64-slice multi-detector CT scanner (Lightspeed VCT, GE Healthcare, USA). Patients were scanned at 120 kV and a tube current range of 100 – 300 mA. Tube current modulation was used. In all cases, images were acquired in a cranio-caudal direction.

A control group of 71 patients was scanned using CT protocol A (120 kV, filtered back projection (FBP), NI: 2.8 = reference NI). 86 patients were scanned using CT protocol B1 (120 kV, 20 % ASIR, NI: 4). By default, the use of 20 % ASIR results in a tube current reduction of approximately 20 %. The raw data are analyzed using the FBP and the ASIR algorithms, resulting in blended images of 20 % ASIR and 80 % FBP. In group B2, raw data from group B1 were blended using 40 % ASIR and 60 % FBP. Due to technical reasons, only 74 of 86 patients could be re-blended for group B2. In group C1, 30 % ASIR was used on 20 patients (120 kV, 30 % ASIR,

NI: 6). In group C2, raw data from group C1 were blended using 50% ASIR and 50% FBP.

**Data Reconstruction**

ASIR is an algorithm-based protocol for reconstructing CT images with a focus on noise reduction. It uses the information obtained from the FBP algorithm as a basis for further transformation. The values of each pixel (y) are transformed using matrix algebra to obtain a new estimate of the pixel value (y*), which is then compared with the ideal value predicted by the noise model. Iterative steps are performed until the final estimated and the ideal pixel values ultimately converge [8]. This method allows for selective subtraction of noise from a CT image.

The tool traditionally used to define desired image quality in the user interface in GE scanners is called the noise index (NI). The NI is referenced to the HU standard deviation in a specific size water phantom, which is compared to the attenuation measured in the CT scout. Lowering the noise index leads to lower noise but requires a higher tube current. When using ASIR, however, a second option to modify tube current is introduced. In a first step the operator chooses the level of ASIR in 10% increments from 0% to 50%. By default, the use of X% ASIR results in a tube current reduction of approximately X% during the scan. Obviously it is possible to choose values for NI and ASIR which mutually exclude each other: e.g. very low NI and a high level of ASIR or vice versa. In such cases of conflicting NI and ASIR values, the system prioritizes the NI over ASIR. This means that ASIR cannot modify tube current when an insufficient NI is chosen. When the noise index is increased, tube reduction may be higher than expected based on the level of ASIR chosen.

After the scan, raw data are reconstructed alternately using ASIR and FBP. ASIR- and FBP-reconstructed images are then combined in a ratio of X% ASIR and 100-X% FBP – e.g. when using 20% ASIR, tube current is reduced approximately by 20%, raw data are reconstructed using ASIR and FBP and finally images are blended using 20% ASIR and 80% FBP. However, after image acquisition different blending ratios can be used (as we have done in groups B2 and C2).

**Image Quality**

Image quality was assessed quantitatively and qualitatively. Quantitative image quality was evaluated as signal attenuation (SI) measured in Hounsfield units (HU) and noise (i.e., standard deviation (SD) of attenuation). We chose regions of interest (ROIs) in the lentiform nucleus (ROI1), frontal white matter (ROI2), temporal cortical layer (ROI3), ventricle (ROI4), internal capsule (ROI5), cortical layer of cerebellum (ROI6), WM of the middle cerebellar peduncle (ROI7) and the vermis (ROI8). The contrast-to-noise ratio (CNR) was calculated according to the following equation:

\[
\text{CNR} = \frac{\Delta(SI_{ROIa} - SI_{ROIb})}{\sqrt{(SD_{ROIa})^2 + (SD_{ROIb})^2}}
\] (2)

CNRs were calculated in the supratentorial (ST) region between ROI3/ROI2 (ST—CNR C/WM) and between ROI1/ROI2 (ST—

For the infratentorial (IT) CNRS we chose ROI6 / ROI7 (IT—CNR C/WM) and ROI8 / ROI7 (IT—CNR V/WM). Two experienced radiologists with 5 and 11 years of experience performed qualitative analysis of the acquired images in a blinded fashion after a joint training session. All technical information was removed from the images to reduce expectation bias. Image quality was evaluated in seven categories: noise, supratentorial contrast between cortex and white matter, supratentorial contrast between lentiform nucleus and internal capsule, infratentorial contrast between cortex and white matter, artifacts, overall diagnosability and diagnostic confidence (in patients with diagnosed acute pathology). Each category was evaluated using a five-point Likert scale where the reference was an “ideal exam”:

**Radiation Dose**

Dose-length products (DLPs) and the computed tomography dose index (CTDIdvol) were acquired. The effective dose (mSv) was estimated by multiplying the dose-length product by a conversion factor of 0.0021 mSv·mGy⁻¹·cm⁻¹ [14].

**Statistical Analysis**

The data were analyzed using GraphPad Prism version 5.0f for Mac (GraphPad Software, San Diego, California, USA) and IBM SPSS Statistics 19 (New York, USA). Continuous data were analyzed using the Student’s t-test, and ordinal data were analyzed using the Mann-Whitney U-test. A p-value of less than 0.05 was considered statistically significant. Interobserver agreement between the two readers was assessed using the Cohen’s kappa test.
Results

Patient Characteristics

Patient characteristics are summarized in Table 2. The groups were well balanced in terms of age, male-to-female ratio or cranial diameter.

Of the 157 patients referred for cranial CT scans from the emergency department (groups A and B), 22.3 % showed acute or subacute pathologies, such as acute bleeding or subacute ischemia and 23.6 % showed chronic pathologies (status post-tumor resection, postischemic scarring), and 54.1 % had no pathology (Table 2). Of the 20 neurological ICU patients referred for follow-up imaging (group C), 75 % showed acute bleeding, 5 % showed subacute ischemia, 5 % had undergone tumor resection, and 15 % were referred due to other pathologies.

The groups were well balanced with respect to age, male/female ratio and cranial diameter. The high number of patients with no intracranial pathology underlines the necessity to keep the level of ionizing radiation as low as reasonably possible.

The Gruppen waren ausgeglichen in Bezug auf Alter, Geschlechtsverhältnis und Kopfdurchmesser. Die hohe Anzahl an Patienten ohne intracranielle Pathologie unterstreicht die Notwendigkeit, die Dosis ionisierender Strahlen so niedrig wie möglich zu halten.

</table>

Compared to group A (control), group B1 showed reduced SNRs and CNRs. Group B2 showed SNRs comparable to group A (except for the infratentorial white matter/vermis CNR). CNR levels were the lowest in group C1. Most SNRs and CNRs increased slightly in group C2 compared to group C1. SNR = signal to noise ratio; CNR = contrast to noise ratio. ST-CNCR (C/WM) = supratentorial CNR (cortex/white matter), ST-CNCR NL/WM = supratentorial CNR (lentiform nucleus/white matter), IT-CNCR (C/WM) = infratentorial CNR (cortex/white matter), IT-CNCR NL/WM = infratentorial CNR (lentiform nucleus/white matter). Lentiform nucleus (ROI1), frontal white matter (ROI2), frontal cortical layer (ROI3), ventricle (ROI4), internal capsule (ROI5), infratentorial ROIs included the cortical layer of the cerebellum (ROI6), WM of the middle cerebellar peduncle (ROI7) and the vermis (ROI8).

These results underlie the necessity to keep the level of ionizing radiation as low as reasonably possible.

Noise, supratentorial and infratentorial contrast were significantly reduced in group B1 and also in group B2, albeit to a lesser extent. Diagnosis-related confidence was not compromised in either group. Group C1 showed significantly poorer results in terms of noise levels, contrast, diagnostic confidence and overall diagnosability, compared to groups A and B1/2. Group C2 showed only slightly better results than group C1. The interobserver agreement was excellent (>0.75) for grading image noise, contrast and overall diagnosability and good (0.4) for overall diagnostic confidence and diagnostic confidence in patients with bleeding. The interobserver agreement in diagnostic confidence in patients with subacute stroke was lower but still acceptable. Interobserver agreement κ cannot be calculated for artifacts because both observers assigned a score of 5 for this parameter to all CTs in all groups.

Compared to group A (control), group B1 showed significantly reduced supratentorial and infratentorial SNRs and supratentorial CNRs. The infratentorial CNRs were either significantly or almost significantly reduced in group B1.

When the ratio of ASIR blending was further increased, there is a growing discussion on radiation dose. Table 5 presents the results of the qualitative analysis of image quality and interobserver agreement.

Discussion

With the number of emergency CT scans performed worldwide increasing constantly, there is a growing discussion on radiation dose.
tion-associated risks [15]. In this study, approximately three quarters of patients referred for cranial CT from the first-aid department had no acute or subacute pathology and almost half of them did not show any pathology whatsoever. Due to the carcinogenic potential of ionizing radiation, cCTs should thus be performed with the lowest radiation dose that still allows adequate diagnosis especially when younger patients are examined.

The implementation of IR algorithms is particularly noteworthy in this context. Several studies have shown that IR algorithms significantly reduce dose while maintaining, or in some cases even improving, image quality [8, 9, 16–18].

The results of our study show that use of a CT protocol with 20 % ASIR reduces the dose of cranial CT by 40.4 %. When combined with blending of 40 % ASIR/60 % FBP, supratentorial CNRs are comparable to those of the control group and infratentorial CNRs remain acceptable. Subjective quality levels, e.g. contrast, overall diagnosability and diagnostic confidence, are also still acceptable. We now routinely use this CT protocol in patients referred from the emergency department in our clinic.

A CT protocol with 30 % ASIR and an increased noise index degrades both quantitative and qualitative image quality to such an extent that it is unacceptable in everyday clinical practice. However, the quality remains high enough for the diagnosis of life-threatening conditions, such as acute bleeding, or brain edema or for the assessment of hydrocephalus especially when blending is increased to 50 % ASIR/50 % FBP. In these cases, this protocol achieved sub-millisievert scanning (0.43 ± 0.20 mSv), which is particularly useful for the repeated follow-up examination of neurosurgical ICU patients.

One of the first studies investigating the use of ASIR in adult cranial CT was conducted by Kilic et al. [11]. In this study, the authors showed a 31 % DLP reduction of cranial CT scans when 30 % ASIR was applied during acquisition. There was no significant reduction in image quality and interpretability (adult patients, 49 FBP cCTs, 98 ASIR cCTs).

Ren et al. investigated the potential role of ASIR in cCTs of adults over 50 years of age. They showed a 30 % dose reduction in 200 mAs cCTs with 50 % ASIR blending compared to 300 mAs cCTs.

Using 20 % of ASIR (group B1 and group B2) led to a significant reduction in the ED of 40.4 % compared to group A. Using 30 % of ASIR during the scan (group C1 and group C2) reduced the ED by 73.3 %.

Die Anwendung von 20 % ASIR (Gruppe B1 und Gruppe B2) führte zu einer signifikanten Reduktion der effektiven Dosis um 40,4 % im Vergleich zur Kontrollgruppe. Die Anwendung von 30 % ASIR (Gruppe C1 und Gruppe C2) führte zu einer signifikanten Reduktion der effektiven Dosis um 73,3 %.

The results of our study show that use of a CT protocol with 20 % ASIR reduces the dose of cranial CT by 40.4 %. When combined with blending of 40 % ASIR/60 % FBP, supratentorial CNRs are comparable to those of the control group and infratentorial CNRs remain acceptable. Subjective quality levels, e.g. contrast, overall diagnosability and diagnostic confidence, are also still acceptable. We now routinely use this CT protocol in patients referred from the emergency department in our clinic.
They evaluated diagnostic confidence but provided no information on noise indices. Unfortunately, NIs were not reported by Ren et al.

A possible explanation could be the use of different scan. In our study, the use of 30% ASIR led to a higher dose reduction compared to FBP reconstruction (age > 50y, 40 patients) [19]. A reduction of the tube current time product from 300 mAs to 200 mAs roughly corresponds to the use of 30% ASIR default settings during the scan.

We found that using 30% of ASIR during the scan (group C1/2) reduced the ED by 73.3%. Using 20% of ASIR (group B1) led to a significant reduction of ED of 40.4% compared to group A. Using 30% of ASIR during the scan (group C1/2) reduced the ED by 73.3%.

To our knowledge, the work presented here is one of the largest and most sophisticated studies on iterative reconstruction in cranial CT. De-
spite the relatively high number of scans performed, no study in this field has yet put an emphasis on emergency department patients or analyzed the frequency of different pathologies. Also, no earlier investigators have performed subgroup analysis of different pathologies. Finally, it has to be mentioned that other publications have not distinguished between infra- and supratentorial image quality in subjective and objective image analysis.

Our study has several limitations. Firstly, no explicit patient group matching was done. However, the patient parameters matched well in terms of age, gender or head diameters.

Secondly, image quality evaluation was based on the subjective impression of two readers and qualitative analysis may indeed not have been completely blind, since an experienced radiologist may identify an ASIR image by its typical appearance. However, we also performed objective quantitative image analysis to corroborate qualitative evaluation. Nevertheless, it has been questioned whether quantitative measures are the appropriate tool for evaluating the effectiveness of IR algorithms. Jensen et al. showed that lesion detection in a liver phantom was not improved in ASIR-reconstructed images compared to FBP-reconstructed images of a liver phantom even though the noise decreased and the CNR increased significantly [22].

Thirdly, patients with foreign material in the skull were excluded in groups A and B1/2 but not in group C1/2, which might have influenced the noise levels in group C1/2.

Conclusion

IR algorithms are a promising option for reducing radiation exposure without compromising image quality in cranial CT. A CT protocol with a combination of 20% ASIR and a 40% ASIR/60% FBP blending ratio decreases the effective dose significantly by 40.4%, while producing scans with similar image quality compared to a routine dose CT. This CT protocol is recommended for evaluating the effectiveness of IR algorithms. Nevertheless, it has been questioned whether quantitative measures are the appropriate tool for evaluating the effectiveness of IR algorithms. Jensen et al. showed that lesion detection in a liver phantom was not improved in ASIR-reconstructed images compared to FBP-reconstructed images of a liver phantom even though the noise decreased and the CNR increased significantly [22]. Thirdly, patients with foreign material in the skull were excluded in groups A and B1/2 but not in group C1/2, which might have influenced the noise levels in group C1/2.

Clinical Relevance of the Study

- The use of computed tomography has been constantly increasing and leads to higher doses of ionizing radiation in the population.
- The routine use of 20% ASIR cCTs with 40% ASIR/60% FBP blending may lead to a dose reduction of more than 40% in these cCTs without compromising diagnosis-related confidence.
- 30% ASIR cCTs with 50% ASIR/50% FBP are adequate for follow-up imaging and offer a dose reduction of over 70% in these cCTs.
