Introduction

Autoimmune pancreatitis (AIP) was first described by Sarles et al. in 1961 as “primary inflammatory sclerosis” of the pancreas.¹ However, later it was identified as distinctive subtype of chronic pancreatitis caused by autoimmune inflammatory processes with heavy lymphocyte infiltration and fibrosis that result in organ dysfunction by Yoshita et al. in 1995.²

It is a rare form of chronic inflammatory pancreatic disease with unclear etiology, but autoimmune mechanisms, genetic susceptibility, and exposure to environmental factors are favored. AIP has two distinct types—type I is considered as pancreatic manifestation of immunoglobulin (IgG4)-related multisystem disease, while type II is considered as isolated pancreatic disease independent of IgG4.³⁴

On imaging, involvement of pancreas can be either diffuse, focal, or multifocal. Focal form of AIP typically presents with clinical and radiological manifestations mimicking pancreatic cancer.³⁶

Here, we report clinical and imaging features that assist differentiation of type I and type II AIP and also help to differentiate focal form of both types of AIP from pancreatic cancer.

Case Discussion

Case 1

A 62-year-old nonalcoholic male presented in gastro-surgery department with chief complaints of backache and mild abdominal pain since 6 to 7 months without significant weight loss and anorexia. Physical examination showed slight deep tenderness in epigastrium; no lump was palpable.
Ultrasonography of abdomen showed a fairly defined hypoechoic mass with necrotic area in head of pancreas and suprapancreatic region with normal diameter of main pancreatic duct (MPD). There was another hypoechoic mass encircling lower part of abdominal aorta and bilateral common iliac arteries.

Triphasic contrast enhanced computed tomography (CECT) of abdomen revealed a hypodense mass lesion in the head of the pancreas and suprapancreatic region with necrotic area in its inferior aspect. It appeared hypodense on arterial phase with inhomogeneous mild enhancement on portal venous phase and appeared iso dense on delayed phase (Fig. 1A and B). Additionally, a poorly enhancing soft tissue density lesion encircling lower part of abdominal aorta and bilateral common iliac arteries (Fig. 2) with mild atheromatous changes involving adventitia of abdominal aorta and iliac arteries. A pancreatic malignant lesion with differential diagnosis of lymphoma or retroperitoneal fibrosis along abdominal arteries was given on the basis of contrast enhanced CT scan findings.

Serum levels of cancer antigen (CA) 19.9 and carcinoma embryonic antigen (CEA) were 2.6 (normal range: 0–37 U/mL) and 0.98 ng/mL (normal value: <2.5 ng/mL), respectively, and mean blood sugar was 114 mg/dL.

Ultrasound-guided biopsy (Fig. 3) from pancreatic mass lesion showed fibrosis with inflammatory infiltrate with no evidence of malignancy (Fig. 4). Serum IgG4 level was 180 mg/dL (normal range: 8–140 mg/dL).

Case 2
A 35-year-old nonalcoholic male presented with chief complaints of off and on pain in abdomen for the last 6 to 7 months with 5 kg loss of weight, yellowish discoloration of urine, and significant loss of appetite for the last 4 months. He was also recently diagnosed with diabetes mellitus. Physical examination showed slight deep tenderness in epigastrium as well as severe icterus.

Total serum bilirubin was 10.2 (direct: 6.6 mg/dL, indirect: 4.0 mg/dL) with serum levels of CA 19.9 and CEA of 103 U/mL and 1.5 ng/mL, respectively. Mean blood sugar levels were 296 mg/dL and glycosylated hemoglobin was 10.6.

Ultrasonography of abdomen showed a fairly-defined hypoechoic mass with prominent MPD. The common bile duct was significantly dilated with its diameter 17 mm and abrupt cutoff at the level of head of pancreas. Mild prominence of intrahepatic biliary radicals was also observed.

Triphasic CECT scan showed focal isoenhancing ill-defined lesion seen in head of the pancreas. Additionally, the scan showed the bulky distal body and tail of pancreas with peri-pancreatic thin rim of fluid collection (Fig. 5A and B). Since the features of CECT scan were equivocal, magnetic resonance imaging (MRI) was done.

Noncontrast MRI of upper abdomen showed mildly hyperintense mass lesion in head of the pancreas (Fig. 6A). MRI also showed bulky tail of pancreas with thin hypointense rim seen around distal body and tail of pancreas (Fig. 6B). The lesion showed restriction on diffusion-weighted imaging with apparent diffusion coefficient (ADC) value ranging from 0.8 to 1.1 x 10⁻³ (Fig. 7).

Biliary stenting was done after endoscopic retrograde pancreatography and brush cytology was done from ampulla that was negative for malignant cells. Ultrasound guided biopsy from pancreatic head lesion revealed no evidence of malignancy. Serum IgG4 levels were within normal range.

Discussion
AIP is a distinct form of pancreatitis characterized clinically by frequent presentation with obstructive jaundice with or without a pancreatic mass, histologically by
AIP accounts for 5 to 6% among all chronic pancreatitis. Men are affected at least twice as often as women, with a reported male-to-female ratio as high as 15:2. The age at presentation ranges from 14 to 85 years, with the mean age over 60 years. In our report, both were male patient of 65 and 37 years, respectively.

Focal forms (mass mimicking) AIP accounts for approximately 5 to 11% of Whipple’s resections done with a suspicion of pancreatic adenocarcinoma. However, with increasing reports of AIP patients in literature, it is possible to diagnose these patients timely preoperatively avoiding unnecessary surgery and associated morbidity.

Typical clinical manifestations of AIP include fluctuating obstructive jaundice, vague abdominal pain, weight loss, occasionally steatorrhea, and diabetes. Diabetes (usually type II) is present in 43 to 68% of patients. In present report, patient with type II AIP (case 2) had type II diabetes.

**Types of AIP**

AIP is divided into type I and II, each one has distinct histopathology, clinical features, and different diagnostic criteria. In 2011, International Association of Pancreatology developed International Consensus Diagnostic Criteria (ICDC) for AIP and proposed two distinct histological of AIP. Type I AIP is also called lymphoplasmacytic sclerosing pancreatitis (LPSP) or AIP without granulocyte epithelial lesions (GEL). LPSP is characterized infiltration of tissue by IgG4 plasma cell with storiform fibrosis and phlebitis. Type II AIP is also defined as idiopathic duct-centric pancreatitis (IDCP) or AIP with GEL.

Histologically, type II AIP is characterized by neutrophilic infiltration of epithelium and lumen of pancreatic duct. Type I AIP (LPSP) seems to be the pancreatic manifestation of an IgG4-related systemic disease and it is characterized by elevated IgG4 serum levels, infiltration of IgG4-positive plasma cells, and extrapancreatic lesions (e.g., sclerosing cholangitis, sclerosing sialadenitis, and retroperitoneal fibrosis). Type I AIP is three times common in males than in females and often seen in sixth decade.

Type II (IDCP) usually has none or very few IgG4-positive plasma cells, no serum IgG4 elevation, and appears to be a pancreas-specific disorder without extrapancreatic...
Type II AIP is commonly seen in younger patients between 20 and 50 years with mean age 45 years without any gender preponderance. It is often associated with inflammatory bowel disease and with diabetes.\textsuperscript{10,11,14,15} IgG4-related sclerosing disease can involve various organs including biliary tree, kidneys, gallbladder, retroperitoneum, mesentery, blood vessels, lungs, orbits, lymph nodes, salivary glands, thyroid gland, and prostate gland.\textsuperscript{12,14}

Retroperitoneal fibrosis is present in about 10 to 20% of patients with type I AIP and it is characterized by a thick soft-tissue mass that is confined to the retroperitoneum and pelvic brim and typically covers the abdominal aorta.\textsuperscript{14}

In present report, the first case of elderly gentleman had focal involvement of pancreatic head, retroperitoneal fibrosis, and elevated serum IgG4 levels suggesting type I AIP with both pancreatic and retroperitoneal fibrosis as IgG4-related extra-pancreatic manifestation.

However, second case of a young male showed an isolated involvement of pancreas with normal IgG4 levels. No extra-pancreatic manifestations were observed that signifies type II variety of AIP.

Elevated serum IgG4 levels are characteristic in AIP but serum IgG4 serology is not the sole criteria to differentiate AIP from pancreatic carcinoma. More than 20% of all AIP have normal Ig4 levels, particularly type II AIP and nearly 7 to 10% of the patients of pancreatic carcinoma have elevated IgG4 levels.\textsuperscript{13} Types of AIP have been summarized in Table 1.

### Imaging Characteristics

Three distinct patterns of AIP are recognized in literature: diffuse, focal, and multifocal.\textsuperscript{11,12,14,16} Diffuse form is the commonest pattern, characterized by “sausage-like” pancreatic enlargement with sharp margins and loss of the lobular contour, while focal form is less common that accounts for 33 to 41% of all cases of AIP.\textsuperscript{16} Multifocal involvement is least common form of AIP, it can involve head, body, or tail of pancreas with presence of multiple areas of pancreatic duct narrowing.\textsuperscript{11,16} Pancreatic head

---

**Fig. 5** (A) Triphasic contrast-enhanced computed tomography (CECT) shows iso enhancing bulky lesion in head of the pancreas (arrowhead). (B) Triphasic CECT scan shows bulky distal body and tail of pancreas with hypodense perifocal rim (marked by arrow).

**Fig. 6** Axial T2-weighted magnetic resonance imaging (T2W MRI) (A) shows mildly hyperintense mass lesion in head of pancreas with proximal dilatation of biliary duct (large arrow and arrowhead, respectively). Axial T2W MRI (B) shows bulky tail of pancreas with hypointense “capsule rim sign” (small arrow), and T2WFS image (C) shows focal mildly hyperintense mass lesion in head of pancreas on T2WFS images (arrow).

**Fig. 7** Axial diffusion-weighted imaging and apparent diffusion coefficient (ADC) map shows diffusion restriction (small arrow) in lesion of head of the head of pancreas with ADC value $0.87 \times 10^{-3}$ mm$^2$/s.
In six out of nine patients, the lesions were hypoattenuating in enhancement pattern of a focal form of AIP in nine patients. ≤ 0.87 x10⁻³ mm²/s. In present report, in both the cases 5 out of 7 patients had decreased enhancement in the pancreatic phase and minimal change in enhancement in the hepatic phase. This finding may help differentiate the focal form of AIP from pancreatic carcinoma.

In present case report, one patient showed hypoattenuation in pancreatic phase, while another patient showed isoattenuation in pancreatic phase and both showed iso-enhancement in delayed phase.

On MRI, focal forms of AIP show T1 hypointensity and mild T2 hyperintensity. MRI shows “capsule rim” sign more accurately. AIP tends to have greater diffusion restriction with lower ADC values as compared to pancreatic adenocarcinoma and normal pancreatic parenchyma. The average ADC value suggested in AIP is ≤ 0.87 x10⁻³ by Muhi et al. Similarly, Kamisawa et al also found lower ADC values in AIP patients (1.012 ± 0.112 x 10⁻³ mm²/s) than in pancreatic cancer patients (1.2496 ± 0.113 x 10⁻³ mm²/s).

In present report, second patient (type II AIP) showed “capsule rim sign,” focal mild T2-weighted hyperintensity, and ADC value in focal lesion is significantly lower than 0.87 x 10⁻³ mm²/s.

Dynamic MRI with secretin administration has potential role in differentiation from benign inflammatory stricture of MPD in AIP from obstructive stricture of pancreatic adenocarcinoma. Patency of inflammatory duct can be demonstrated after secretin stimulation that is known as “duct penetrating sign.” Difference between AIP and pancreatic carcinoma has been shown in schematic diagram (Fig. 8).

Conventional endoscopic ultrasonography (EUS) plays an important in identifying small pancreatic lesion. However, EUS-guided fine-needle aspiration has limited role in diagnosis of nonmalignant pancreatic parenchymal conditions; therefore, image-guided percutaneous biopsy preferred when lesion is well demonstrated on imaging studies and in case of smaller lesion or lesion EUS-guided core biopsy can be alternative.

The CT attenuation of the pancreatic lesion AIP is similar to or greater than that of the liver in both the pancreatic and the hepatic phases. Wakabayashi et al evaluated the CT enhancement pattern of a focal form of AIP in nine patients. In six out of nine patients, the lesions were hypothaenattuation in the early phase but were homogeneously isoattenuating in the delayed phase and also suggested that pancreatic carcinoma had decreased enhancement in the pancreatic phase and minimal change in enhancement in the hepatic phase. This finding may help differentiate the focal form of AIP from pancreatic carcinoma.

Abbreviations: AIP, autoimmune pancreatitis; IDCP, idiopathic duct-centric pancreatitis.

is the most common site for the focal involvement in AIP and appears as hypoechoic lesion on ultrasonography. The differentiation is extremely difficult as this appearance is not specific and often seen in pancreatic carcinoma and in other forms of chronic mass forming inflammatory pancreatitis.

Cross-sectional imaging of pancreas is the very important to diagnose AIP. The CT imaging features in AIP include (a) diffuse swelling of the pancreas, which is referred to as a “sausage-like” or “bulky” appearance, (b) a capsule-like smooth rim of low density surrounding the pancreas that appears to be characteristic of AIP and related to inflammatory and fibrotic changes in peripancreatic fat, (c) absence of pancreatic calcification and intraductal stones, and (d) delayed enhancement of affected pancreatic lesion.

Muhi et al defined seven criteria to differentiate mass-forming AIP from pancreatic carcinoma with high accuracy based on CECT/MR in various combinations. This includes (1) early homogeneous good enhancement, (2) delayed homogenous good enhancement, (3) hypoattenuating capsule-like rim, (4) MPD upstream diameter < 4 mm, (5) the absence of distal pancreatic atrophy, (6) “duct penetrating sign”—a result of inflammatory nature of AIP causing duct narrowing as against complete obstruction of duct in pancreatic carcinoma, and (7) ADC value ≤ 0.87 x10⁻³ by Muhi et al. Similarly, Kamisawa et al also found lower ADC values in AIP patients (1.012 ± 0.112 x 10⁻³ mm²/s) than in pancreatic cancer patients (1.2496 ± 0.113 x 10⁻³ mm²/s).

In present case report, one patient showed hypoattenuation in pancreatic phase, while another patient showed isoattenuation in pancreatic phase and both showed iso-enhancement in delayed phase.

On MRI, focal forms of AIP show T1 hypointensity and mild T2 hyperintensity. MRI shows “capsule rim” sign more accurately. AIP tends to have greater diffusion restriction with lower ADC values as compared to pancreatic adenocarcinoma and normal pancreatic parenchyma. The average ADC value suggested in AIP is ≤ 0.87 x10⁻³ by Muhi et al. Similarly, Kamisawa et al also found lower ADC values in AIP patients (1.012 ± 0.112 x 10⁻³ mm²/s) than in pancreatic cancer patients (1.2496 ± 0.113 x 10⁻³ mm²/s).

In present report, second patient (type II AIP) showed “capsule rim sign,” focal mild T2-weighted hyperintensity, and ADC value in focal lesion is significantly lower than 0.87 x 10⁻³ mm²/s.

Dynamic MRI with secretin administration has potential role in differentiation from benign inflammatory stricture of MPD in AIP from obstructive stricture of pancreatic adenocarcinoma. Patency of inflammatory duct can be demonstrated after secretin stimulation that is known as “duct penetrating sign.” Difference between AIP and pancreatic carcinoma has been shown in schematic diagram (Fig. 8).

Conventional endoscopic ultrasonography (EUS) plays an important in identifying small pancreatic lesion. However, EUS-guided fine-needle aspiration has limited role in diagnosis of nonmalignant pancreatic parenchymal conditions; therefore, image-guided percutaneous biopsy preferred when lesion is well demonstrated on imaging studies and in case of smaller lesion or lesion EUS-guided core biopsy can be alternative.
Follow-Up and Treatment

Both subtypes of AIP show dramatic clinical response after oral corticosteroid treatment that is evident by returning of normal morphological and pancreatic functions as well as resolution of pancreatic duct narrowing or irregularity in 4 to 6 weeks. Follow-up with multidetector computed tomography (MDCT) or MRI imaging helps in response evaluation that evaluates the regression in size of pancreatic lesion or regression in bulk of pancreas. However, type I AIP with focal involvement has higher risk of recurrence or poor treatment response.\textsuperscript{19,20} Follow-up MDCT of one our patient (type I) showed mild response to corticosteroid therapy (►Fig. 9A and B). Recently, in corticosteroid resistant or relapse cases of AIP, few immunomodulators such as azathioprine, cyclosporine, and rituximab have been suggested.\textsuperscript{22,23}

Conclusion

AIP is rare but not an exceptional entity. Precise radiological distinction by various imaging features, pattern of contrast enhancement on CT scan, and timely diagnosis of AIP is very crucial to avoid unnecessarily pancreatic resection and major abdominal surgeries; thus, associated comorbidities and speedy recovery are avoided. Clinical and imaging features also helps to differentiate type I and II variety of AIP. It is essential for radiologist to know precise imaging signs of focal forms of both types of AIP to differentiate from pancreatic carcinoma.
