Abstract

Purpose Several studies have been conducted to determine morphometry of lumbar vertebrae, mostly in western population and data on other populations is relatively sparse. Most of these studies have been carried out using fresh cadavers or osteological collections and several of them having limitations such as a small sample size and lack of demographic information. We conducted morphometric analysis of the lumbar vertebrae in a relatively large number of Indian patients using computed tomography scan. Vertebral body and pedicle dimensions of lumbar spinal elements were documented in Indian population and compared with other studies from the subcontinent as well as from other parts of the world. The morphometric data thus compiled may help in the development of new spinal implants for transpedicular screw fixations.

Methods An observational study was conducted and a total of 302 patients were evaluated. Thin section computed tomographic images of the 12th thoracic vertebra (D12) to 1st sacral vertebra (S1) were acquired and various dimensions of vertebral body and pedicle were recorded and analyzed.

Results Generally, the lumbar vertebral and pedicle dimensions were found to be greater in male patients. Comparison of dimensions in different populations revealed statistically significant differences in pedicle dimensions between Indian population and others.

Conclusion Morphometric analysis of lumbar vertebrae using computed tomography scan provides measurements of different vertebral dimensions. This will help in development of spinal implants in future to meet the specific needs of the studied population.
Introduction

Vertebral column forms central axis of the body and it gives main support to bones and muscles. Knowledge of vertebral morphology helps us to understand spine biomechanics. Thorough knowledge of lumbar morphometry is very helpful in correcting deformities and stabilizing the spine with the help of different spinal implants during spinal surgeries or in the setting of trauma. To ensure precise screw positioning, it is essential that the surgeons have an intimate knowledge of spinal anatomy and be able to localize the bony and neural structures accurately while performing the procedure.

In different spinal ailments including trauma transpedicular fixation of the spine is an effective vertebral stabilization method. It is important to achieve proper placement of pedicle screw for a successful outcome in the spinal surgeries. Mismatching of pedicle and screw size may result in serious complications like loosening of the screw, fracture of the pedicle, dural tear, leakage of cerebrospinal fluid, nerve-root injuries. and in worst cases injury to spinal cord itself. Thus, detailed understanding of morphometry of the pedicle is important to prevent potential complications due to use of inappropriate sized pedicle screws.

Several studies have been conducted to determine morphometry of lumbar vertebrae, mostly in western population. Most of these studies have been carried out using fresh cadaver or osteological collections. Moreover, many of these studies have limitations such as a small sample size and lack of demographic data including race, age, and sex. Computed tomographic images have been employed more recently to study lumbar vertebral anatomy. Recent use of computed tomography (CT) for measurement of different vertebral dimensions like pedicle diameter, interpedicular distance, transpedicular angle, and other vertebral dimension has led to better evaluation of vertebral morphometry compared to plain X-rays and cadaveric studies.

In this study, we have conducted morphometric analysis of the lumbar vertebrae in Indian population in a relatively large number of patients by using CT scan. The morphometric data thus compiled may serve as a basis for the development of new spinal implants for transpedicular screw fixations.

Materials and Methods

This observational study was conducted in one of North India’s premier tertiary care institute and this research had been approved by the institutional review board of the authors’ affiliated institutions. A total of 302 patients undergoing CT evaluation in the radiology department were evaluated over a period of 1 year. Patients undergoing diagnostic CT scan for abdominal or genitourinary complaints and patients attending the radiology department for an abdominal CT scan for indications other than the vertebral column pathology during the study period were included in the study. Exclusion criteria included all individuals with age < 20 years or age > 40 years, cases with gross spinal pathology and neurological deficit due to spinal condition, major chronic systemic disease like chronic liver disease and chronic kidney disease, cases of clinically labeled dwarfism, and scans with motion/metallic artifacts.

CT scan was performed using 64-slice multidetector CT scan (Brilliance 190P 64-channel CT scanner, Philips). Noncontrast CT was performed from the level of diaphragm to pubic symphysis with area to be covered (field of view) from D12 vertebral level to the S1 vertebral level. The scan was acquired with slice thickness of 3 mm and then 1 mm thick images were reconstructed in bone window setting from the source data. Then the images were reformatted in axial, sagittal, and coronal planes and analyzed.

In our study, we measured different parameters of each vertebra from D12 to S1 level. For simplicity, we divided these parameters broadly into two groups:

1. Pedicle dimensions (Fig. 1A, 1B and 1D):
   - Pedicle width–distance between medial and lateral surface of pedicle at midpoint.
   - Pedicle height–distance between superior and inferior border of pedicle at midpoint.
   - Interpedicular distance–maximum distance between pedicles.
   - Transpedicular angle–angle between a line passing through the center of the pedicle in longitudinal axis and a line parallel to the vertebral body midline.
   - CT ratio–pedicle transverse diameter/mean vertebral body width, expressed in percentage.

Fig. 1 Computed tomography (CT) lumbar vertebra in axial (A, B), mid-sagittal (C), and parasagittal (D) planes depicting pedicle width (E, F), interpedicular distance (G, H), vertebral width (I, J), vertebral depth (K, L), transpedicular angle (x-y-z), anterior (M, N) and posterior (O, P) vertebral height, and pedicle height (Q, R).
2. Vertebral body dimensions (Fig. 1A and 1C):

Upper and lower vertebral depth–distance between anterior and posterior surface of vertebral body in the plane of the upper and lower endplates, respectively.

Upper and lower vertebral width–distance between the lateral borders of the vertebral body in the plane of the upper and lower endplates, respectively.

Anterior vertebral body height–distance between the upper and lower endplates of vertebral body at anterior margin.

Posterior vertebral body height–the distance between the upper and lower endplates of vertebral body at posterior margin.

Data was processed and analyzed on SPSS version 17 (SPSS Inc.; Chicago, Illinois, United States), with p-value of 0.05 set to be significant. “Unpaired t-test” was used to compare different dimensions of lumbar spine of Indian patients with other population and “independent t-test” was used to compare between male and female population.

Results

Out of 302 patients studied, 174 (57.6%) were male and 128 (42.4%) were female. Note that 176 (58.3%) of them were between the age of 20 and 30 years and 126 (41.7%) were between the age of 31 and 40 years.

1. Pedicle dimensions (Table 1):

Mean pedicle width consistently increased from L1 to L5 in both males and females. The maximum mean pedicle width was at L5 and minimum at the L1 level. The pedicle width was significantly (p < 0.05) greater in males compared to females. Pedicle height decreased marginally from D12 to L4 followed by increase at the L5 level in both males and females. The minimum pedicle height was noted at L4 and maximum at D12 level. The pedicle height was significantly (p < 0.05) more in males compared to females at all levels.

Table 1 Measurements (in mL) of mean ± SD of pedicles width, pedicles height, interpedicular distance, and transpedicular angle (in degree) in males (M) and females (F)

### Discussion

There are multiple studies in the literature on the anatomic and radiographic morphometry of the lumbar spine. However, the values vary significantly across races, genders, and study groups. Majority of studies available have been performed in non-Asian population. Very limited data regarding the anatomic detail of lumbar spine is available among Asian population.21-25 On review of literature there are multiple studies on Indian population of different regions; however, several of these studies have limitations such as small sample size and lack of information on demographic data like race, age, and sex.24-30 Differences have been reported between Indian and the western population by Chadha. et al and Acharya. et al on the different dimension of lumbar vertebrae, but these studies did not mention the differences between male and female vertebral parameters and also these studies were conducted on relatively small sample size.24-25 This necessitated the need for morphometric analysis of the lumbar spine among Indian population. Our study compiled morphometric data of lower thoracic and lumbar vertebrae (from D12 to S1 vertebra) in an Indian population by CT-based measurements which were more clinically relevant and accurate in contrast to cadaveric or manually measured data. The present study provides a comparison with other Indian, Asian, as well as western population and also provides comparison between males and females. The morphometry of lumbar vertebrae thus obtained will provide necessary parameters for developing accurate size spinal implants and pedicle screws for Indian population in future.

1. **Pedicle dimension:**

   In our study, we noted that mean pedicle width increased gradually from L1 to L5 level with maximum mean pedicle width at L5 and minimum at L1 level. The pedicle width diameters were smaller in female at all levels. Various other studies showed similar trends but ours is the largest series and compared both males and females of Indian population (Table 3). Multiple international studies from Asian countries which showed similar trends include one of Alam et al, where they conducted CT-based measurements of lumbar vertebrae on 49 patients in Pakistan.22

   The pedicle height progressively decreased from D12 to L4 then increased at L5 both in males and females and the pedicle height was greater in males. Various studies showed similar results like by Sreevidya et al and Singh et al, but these were cadaveric studies.31-35 Few studies like that of Arora et al and Seema. et al found that the pedicle height gradually increased from L1 to L5 level.5,10 This was in contradiction to our study. Alam. et al in Pakistani population showed pedicle height decreased from L1 to L5 level.22 Wolf. et al in Israeli population showed that the pedicle height decreased from L1 to L3 then increased at L4 and L5 level.21 This pattern was slightly different from our study. Interpedicular distance increased from D12 to L5 level in both males and females. Similar patterns were seen in various studies done in other populations, however, absolute measurements differed (Table 4).

   CT ratio (pedicle transverse diameter/vertebral body transverse diameter, expressed in percentage) decreased marginally from D12 to L2 followed by increase from L3 to
CT Morphometry of Lumbar Spine in Indian Population

Singh et al.

Indian Journal of Neurotrauma

L5 level. The maximum value was noted at D12 and minimum at L2 level (Table 5). Till now “CT ratio” as a parameter was only documented in Korean population by Kang et al, where they used maximum transverse diameter of vertebral body as the denominator.21 They measured CT-based dimensions of lumbar vertebrae of 50 patients and showed the maximum CT ratio at L5 (31.13%) and minimum at L2 (20.46%). The authors in the study on Korean population observed that there was definite correlation between vertebral width and pedicle width measured by CT at specific vertebral level. Vertebral width can be measured with reasonable accuracy on plane radiograph taken in true anteroposterior (AP) projection. However, since pedicles are obliquely placed structures, it is not possible to know its accurate dimensions on AP or lateral radiographs. Thus, by knowing the CT ratio beforehand at specific vertebral levels

and vertebral width measured on AP radiographs, one can very well estimate the pedicle width at that vertebral level. In our study, we used mean of upper and lower vertebral body width as the denominator and measured the “CT ratio” in the Indian population. Similar pattern was seen in our study; however, our values were higher than those documented in Korean population.

2. Vertebral dimension:

Anterior vertebral body height gradually increased from D12 to L3 level, marginally decreased at L4 followed by an increase at L5 and S1 level in both males and females. Similar results were recorded by Singh. et al in 20 cadavers in North Indian population.26 Wolf et al11 in his study observed that anterior vertebral body height gradually increased from L1 to L5 which was different from our results (Table 6). Alam. et al showed that the anterior vertebral body height increased from L1 to L3 in male and female population of Pakistan as depicted in our study.22 Posterior vertebral body height gradually increased from D12 to L3 followed by progressive decrease from L3 to S1 level in both males and females (Table 7).

Cadaver study on Indian patients by Singh. et al and CT morphometry in Pakistani population by Alam. et al mentioned similar pattern of posterior vertebral body height measurements in both males and females.21,26

Upper vertebral depth increased from D12 to L5 then it decreased at S1 in both males and females. Similar pattern was observed by Alam. et al in Pakistani population in both males and females. Also, the values of upper vertebral depth were greater in males compared to females at all levels similar to our study.22

Upper vertebral width increased from D12 to S1 in both males and females. Similar results were found by Singh. et al on 20 cadaveric study.26 Alam. et al in Pakistani population and Kang. et al in Korean population CT morphometry, observed similar trends of increase of upper vertebral width cranio-caudally from L1 to L5.22,23 Lower vertebral width increased from D12 to L5 but decreased at S1 level.

in both males and females. Similar study by Singh. et al on 20 cadavers in North Indian population noted that lower vertebral width increased from L1 to L2 then decreased at L3 followed by an increase at L4 and L5 levels.26 This pattern was not seen in our study. The study of Alam. et al on Pakistani population showed similar patterns in both males and females as seen in our study with lower vertebral width greater in males.22 So our study results are very similar to Pakistani population study results for pedicle and vertebral body dimensions but not to other Asian population where statistically significant differences were noted.

Conclusion
The limited available data on the anatomical details of lumbar spine for large sample size of Indian and Asian population necessitated need for morphometric analysis of lumbar vertebrae among Indian patients. Computed tomographic image evaluation for lumbar morphometry is clinically more relevant and accurate than cadaveric or manually measured data. This study may provide necessary parameters for developing accurate size spinal implants and pedicle screws for Indian population in future.
