Abstract

Objective This study aimed to investigate the effects of alendronate (ALN; a bisphosphonate) on adhesion and viability of preosteoblasts using different cell passages on sandblasted and acid-etched (SLA) Ti surfaces.

Materials and Methods Preosteoblast, MC3T3, cells (passage 42; P42 and passage 62; P62) were cultured with ALN (1 and 5 μ M) on cell culture plate for 7 days. Cells were lifted, counted, and seeded on SLA Ti surfaces. Cells were incubated on the discs for 6 hours to examine cell adhesion by using confocal microscopy and for 24 hours to determine cell viability by using MTT assay.

Results ALN interfered with cell adhesion on Ti surfaces by reducing the cell number in both cell passages. Nuclei of untreated cells showed oval shape, whereas some nuclei of ALN-treated cells demonstrated crescent and condensed appearance. ALN at 1 and 5 μ M significantly decreased nuclear area and perimeter in P42, while ALN at 5 μ M reduced nuclear area and perimeter in P62. After 24 hours, cells (P42) grown on Ti surfaces showed decreased cell viability when culturing with 5 μ M ALN.

Conclusion ALN reduced cell adhesion and viability of preosteoblasts on Ti surfaces. ALN treatment seemed to exert higher inhibitory effects on nuclear shape and size as well as cell viability in lower cell passage. This led to the reduction in cell to implant surface interaction after encountering bisphosphonate treatment.

Introduction

The rehabilitation with dental implants for replacing teeth has become more attractive and efficient than conventional fixed and/or removable prosthesis. The implants have been inserted in patients of all ages, especially in the elders. Patients receiving a drug called bisphosphonate may

also acquire dental implants for tooth replacement. Dental implant procedure is defined as dentoalveolar surgery, which can increase a risk of developing medication-related osteonecrosis of the jaw (MRONJ) in bisphosphonate-administered patients.^{1,2} Patients who obtain implant placement either during or after bisphosphonate treatment can accelerate the development of MRONJ. The occurrence ranges from 0 to

66 months after implantation.² However, survival rate of dental implant placement in patients receiving bisphosphonate is still controversy.³⁻⁷ Bisphosphonate administration reduces the survival rate of the implants to 86%³ and causes exposure of implant thread.⁸ The implant failure rate in patients taking bisphosphonate is estimated with a risk ratio of 1.73.⁴ On the contrary, several studies report that bisphosphonates do not have a negative impact on implant success rate.⁵⁻⁷

Bisphosphonates have critical impact on bone remodeling process with the primary effect on osteoclasts. Other target cells include osteoblasts.⁹⁻¹¹ Bisphosphonates affect osteoblast viability, differentiation, function, and gene expressions associated with differentiation such as Runx 2 and collagen type I.⁹⁻¹¹ Osteoblasts play an important role in osseointegration by secreting collagen type I and subsequently deposition of hydroxyapatite to form the new bone around the dental implant.¹² Bisphosphonates could interfere with new bone formation/bone healing around the implant by inhibiting osteoblast activities and may subsequently lead to failure of implant placement.

Many studies have reported the effects of bisphosphonates on osteoblast activities grown on cell culture plates as well as epithelial cell and gingival fibroblast adhesion on Ti surfaces.^{9-11,13} However, little is known about bisphosphonate-influenced adhesion and viability of osteoblasts on Ti surfaces. Since dental implant placement is not limited to a certain age, response of different cell passages to bisphosphonates might differ. Therefore, the purpose of this study was to investigate the effects of ALN on pre-osteoblast, MC3T3, adhesion, and viability on the implant surfaces at different passages. MC3T3 cells have been used as in vitro model for studying cell viability and the effects of senescence.^{14,15} According to Chung et al and Peterson et al, MC3T3 cells at passage less than 20 is considered early or low passage, passage 40 to 60 is high passage, and passage more than 60 is considered late or very high passage.^{15,16} This study utilized and modified by using passage 42 and 62 as middle-aged and old cells, respectively. This finding would gain the basic knowledge of the drug effects on cell adhesion and viability on Ti surfaces.

Materials and Methods

Titanium Disc Preparation

A 0.5-mm thick commercially pure Ti grade 4 sheet was cut into 8 mm in diameter discs by using wire cutting machine (Sodick, AQ325L, Japan). Ti discs were blasted with aluminum oxide particles (size 50–270 μm) for 10 seconds. The distance from the tip of the blasting gun and the specimens was 90 mm. The air pressure for sandblasting was set at 0.4 MPa. After sandblasting, specimens were immersed in H_2SO_4 -HCl liquid (45:15% wt) for 10 minutes, sonicated in distilled water for 10 minutes, and then air dried.¹⁷ All specimens were sterilized by ethylene oxide gas. Prior to cell seeding on the Ti discs, the discs were immersed in the α -minimum essential medium (α -MEM; Gibco, New York, United States) supplemented with 10% fetal bovine serum and 1%

penicillin/streptomycin (standard media) overnight for protein adsorption onto the Ti surfaces.

Roughness of specimens was evaluated for the consistency of surface preparation. Three discs were randomly sampled for surface topography testing by using surface profiler (SurfTest, Mitutoyo, United States). The degree of roughness of the substrate surfaces was processed with SURFPAK-SV software (version 1.300) and presented as arithmetical mean deviation of the assessed profile (Ra). Surface profile and the means Ra were shown in ►Fig. 1A and Table 1, respectively. The SLA surfaces of all discs tested had significantly higher roughness than the smooth surface, while there was no roughness difference among the SLA discs.

Cell Culture and Treatments

MC3T3 cells, mouse osteoblast precursors obtained from ATCC (CRL-2593) were cultured in standard media at 37°C and 5% CO_2 . In this study, two cell passages were used: cell passage 42 to 44 and cell passage 62 to 64. These passages were referred to P42 and P62, respectively. MC3T3 cells were first cultured at a density of 50,000 cells/well in six-well culture plates. Cells were treated with ALN at 1 and 5 μM for 7 days. Untreated cells were served as control. After 7 days of treatment, MC3T3 cells were then trypsinized with 0.25% trypsin/EDTA. Cells were counted and 7,500 cells were

Table 1 Surface roughness of smooth and sandblasted and acid-etched surfaces

Surface	Roughness (μm)	p-Value
Smooth	0.12 \pm 0.01	
SLA1	0.69 \pm 0.06	<0.01
SLA2	0.73 \pm 0.02	<0.01
SLA3	0.76 \pm 0.03	<0.01

Abbreviation: SLA, sandblasted and acid-etched.

Note: Values are expressed as mean Ra \pm standard deviation.

seeded on each Ti disc. For cell adhesion and nuclear morphology assays, cells were incubated for 6 hours. For cell viability assay, cells were cultured for 24 hours.

Cell Adhesion and Nuclear Morphology

Cells were cultured as described in “cell culture and treatments.” After seeding on Ti disc for 6 hours, nonadherent cells were removed by gently washing the discs with phosphate-buffered saline (PBS) solution. Cells were fixed with 4% paraformaldehyde for 15 minutes. Cells were permeabilized with 0.1% Triton-X-100 solution (Sigma-Aldrich, Missouri, United States) for 15 minutes. MC3T3 cells were thoroughly washed with PBS and stained with 4',6-diamidino-2-phenylindole dihydrochloride (DAPI; Sigma-Aldrich) at the dilution of 1:1,000 for 5 minutes for nuclear visualization. Cells were viewed under confocal microscopy (Nikon Eclipse Ti, Nikon Instruments). Images of nuclei were captured at $\times 200$ magnification by using NIS element AR 4.11.00 software. The number of nuclei is counted, which represented the number of cell adhesion on Ti discs. ImageJ software (National Institutes of Health version 1.8.0) was used for analyzing the nuclear projected area (μm^2) and nuclear perimeter (μm).

Cell Viability

After seeding the cells on the discs for 1 day, MC3T3 cells were incubated with 0.2% (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide) (MTT) solution (Sigma-Aldrich) at 37°C for 4 hours. The reaction was then stopped with dimethyl sulfoxide (Sigma-Aldrich) and glycine buffer (research organics). The formazan color was then analyzed by measuring the absorbance at 620 nm (A620) with Megellan software, V6.6.

Statistical Analysis

Data presented as means \pm standard deviation. Three independent experiments were conducted. To assess the drug effect at various concentrations, the mean values were compared by one-way ANOVA followed by Tukey's test. Significance was assigned as $*p < 0.05$ and $**p < 0.01$.

Results

Cell Adhesion

To evaluate MC3T3 cell adhesion on Ti surface, confocal imaging of nuclei was assessed in three dimensions (xyz axis). DAPI-positive nuclei, representative of cells, were shown in blue color. In untreated control, adherent cells were seen throughout the surface of Ti discs. Blue nuclei were less confluent in ALN treatments in both P42 and P62, especially at higher concentration ($5\ \mu\text{M}$; **Fig. 2A**).

After 6 hours of cell seeding on Ti surface, approximately 13.5 and 14.5% of untreated cells adhered to the disc surfaces in P42 and P62, respectively (**Fig. 2B and 2C**). ALN affected cell adhesion by decreasing the numbers of nuclei on Ti discs. Both concentrations of ALN ($1\text{--}5\ \mu\text{M}$) significantly reduced the number of cell adhesion when compared with control. The peak reduction was seen at $5\ \mu\text{M}$ ALN treatment. The numbers of adherent cells decreased up to

62 and 65% in P42 and P62, respectively. However, there was no statistically significant difference between 1 and $5\ \mu\text{M}$ ALN groups (**Fig. 2B and 2C**).

Nuclear Morphology and Size

From two-dimensional fluorescence microscopy images, the morphology of DAPI-positive nuclei in untreated control cells were oval shape (**Fig. 3A and 3D**). Some nuclei treated with ALN at $5\ \mu\text{M}$ appeared as condensed and crescent moon shapes as pointed with arrow heads and arrows, respectively (**Fig. 3C and 3F**).

The average nuclear area of P42 control cells was $208\ \mu\text{m}^2$, whereas that of P62 was $163\ \mu\text{m}^2$. ALN at $5\ \mu\text{M}$ significantly decreased nuclear projected area on both P42 and P62 when compared with control group by 23 and 17%, respectively. ALN at $1\ \mu\text{M}$ significantly reduced nuclear projected area over control by 18% only in P42. There were no significant differences between 1 and $5\ \mu\text{M}$ ALN on both P42 and P62 (**Fig. 3G and 3H**). The average nuclear perimeter of P42 control cells was $53\ \mu\text{m}$, whereas that of P62 was $48\ \mu\text{m}$. The result in the nuclear perimeter had a similar trend as that in the average nuclear area. The peak reduction effect was found when treated cells with $5\ \mu\text{M}$ ALN (**Fig. 3I and 3J**).

Cell Viability

MTT assay was used to examine cell viability of MC3T3 cells after 24-hour seeding on titanium discs. In P42, the lowest percentage of cell was found in $5\ \mu\text{M}$ ALN group. This concentration significantly reduced cell viability when compared with control. There was no statistical difference between control and $1\ \mu\text{M}$ ALN group (**Fig. 4A**). In P62, cells treated with $5\ \mu\text{M}$ ALN also displayed the lowest percentage of cell viability; however, no statistical difference was shown among control and experimental groups (**Fig. 4B**).

Discussion

Our study revealed the negative effects of ALN on preosteoblast adhesion, viability, and nuclear size on Ti surfaces. The concentrations used in this study were accounted for free bisphosphonate levels found in saliva or released from bone samples taken from patients with active MRONJ or receiving bisphosphonate.¹⁸ It has been shown that bisphosphonates interfere with adhesion in other cell types. Bone slices pretreated with ALN reduce the number of adherent osteoclast cells.¹⁹ Treatment with ALN at 0.5 to $5\ \mu\text{M}$ for 24 to 48 hours decreases epithelial and gingival fibroblast cell attachment on Ti discs by up to 30%.¹³ In this study, we found higher reduction of cell adhesion on Ti discs by up to 65%. This could be due to the types of cell tested, experimental design, and the duration of treatment (7 vs. 1–2 days).

ALN can cause positive or negative effects on osteoblast viability depending on the concentrations and treatment duration.^{10,20,21} A stimulating effect is seen at low concentrations of ALN ranging from 0.01 to $1\ \mu\text{M}$ on human osteoblast-like cells.^{20,21} On the contrary, the inhibitory effect of ALN is found at higher concentrations ($>5\ \mu\text{M}$) on mouse primary osteoblast cells and human mesenchymal stem cells.^{9,10} The results

of this study showed no difference between cell viability of control and that of low-dose ALN treatment (1 μM). The reduction of viable cells was observed only on cells treated with higher concentration of ALN (5 μM), which is in an agreement with previous study by Patntirapong et al.¹⁰

The inhibition of osteoblast viability by bisphosphonates is reported primarily through the induction of cell apoptosis.^{9,11} One of the hallmarks of cell undergoing apoptosis is the characteristic changes in nuclear morphology.²²⁻²⁴ The early stage of nuclear change starts peripherally along the nuclear membrane, thus forming a crescent-like shape nucleus.²² This is followed by nuclear condensation and fragmentation.²²⁻²⁴ The promotion of apoptosis can be detected by DAPI staining of the nuclei.^{9,23} Then, nuclear shape is monitored and nuclear size is measured.^{23,24} Cancer cells treated with cycloheximide, a potent activator of apoptosis,

demonstrate nuclear shrinkage as shown by diminished nuclear area and perimeter.²³ The changes in nuclear shape and area were observed after treatment with 5 μM ALN. Some nuclei showed sign of early apoptosis (crescent shape), whereas some nuclei illustrated the later stage of apoptotic nucleus (a near spherical shape together with decreasing nuclear size). Furthermore, nuclear projected area data were in accordance with the trend of cell viability. This data support the notion that bisphosphonates cause cytotoxicity to osteoblasts, possibly through the initiation of apoptosis.^{9,11}

ALN reduced cell adhesion, nuclear size, and cell viability in both passages in a similar trend. However, it was noticeable that the percentage of reduction was a little lower in higher passage except for the percentage of cell adhesion. Generally, cell activities begin to decline when cells age. In osteoblasts, cell activities decrease as passage number inc

reases.^{16,25,26} Bisphosphonates are reported to be internalized into cells via endocytosis.²⁷ This cellular process is decreased in aging cells or senescent cells.²⁸ It could be possible that higher passage cells altered in cell response to the drug treatment by internalizing less ALN. However, this speculation needs to be investigated in the future. In addition, the limitation of this study was that only two passages were employed,

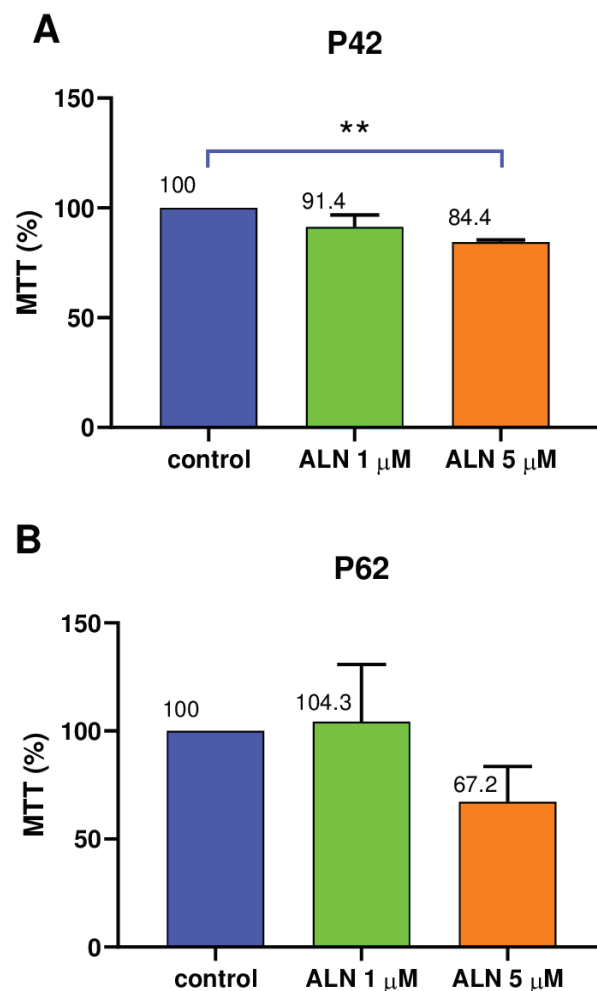

Fig. 4 Reduction of cell viability grown on Ti discs by alendronate. Cell viability were examined by MTT assay after seeding for 24 hours. (A) P42. (B) P62. Values are expressed as mean percentages \pm standard deviation; $**p < 0.01$ versus untreated control; $n = 3$.

and the data might not represent the whole range of other passages.

An implant insertion creates a wound in bone tissue. Naturally, bone tissue regenerates around the implant, thus generating a firm anchoring of an implant. The key factors of bone/Ti implant interaction requires good cell health including cell attachment and viability. Bone surface provides a population of osteogenic cells, while the implant surface relies upon the recruitment and migration of the osteogenic cells. Later on, new bone formation develops on the implant surface (contact osteogenesis), which finally joins with bone formation forming on the host bone (distant osteogenesis; \blacktriangleright Fig. 5A). In bone microenvironment treated with bisphosphonates, osteogenic cells expose to the drug. Uptake of ALN negatively affected osteogenic cells/Ti implant interaction by reducing cell adhesion to the implant surface and cell viability, thus interfering with the interaction process of bone/implant (\blacktriangleright Fig. 5B). It should be noted that the results of in vitro study with bisphosphonates might not be relevant to in vivo occurrence. The data should be interpreted with caution. Patients treated with oral

Fig. 5 A proposed schematic diagram of effects of ALN on preosteoblast adhesion and viability. (A) ALN-free bone microenvironment. (B) ALN-treated bone microenvironment. ALN, alendronate.

bisphosphonates appeared to have good results for implant placement.⁷ However, failure of implant as well as the risk of developing MRONJ still exists.^{2,29} Patients treated with bisphosphonate should be considered with precautions when undergoing implant surgery.^{7,29}

Conclusion

This study revealed negative effects of ALN on preosteoblast viability by the induction of cell apoptosis. ALN also interfered cell adhesion on Ti surfaces. Both cell passages were affected by the drug. The data demonstrated the role of bisphosphonate on bone cell/implant interaction. This should raise awareness when considering an implant placement.
