Abstract

Techniques for symmetrical balancing in flexion and extension have been described; however, the ideal technique is unclear. This study aimed to clarify whether resection of peripheral osteophytes could restore neutral hip–knee–ankle (HKA) angle of varus deformity of arthritic knees. Data from 90 varus arthritic knees that had undergone total knee arthroplasty (TKA) using a nonimage-based navigation system were analyzed. The change in the coronal mechanical axis, while applying manual valgus stress at extension and 90 degrees of knee flexion, was recorded after the following sequential procedures: (1) anterior cruciate ligament (ACL) sectioning, (2) subperiosteal stripping of the deep medial collateral ligament (MCL) from the underlying osteophytes on the medial tibia, and (3) complete removal of peripheral osteophytes from the proximal medial tibia and distal medial femoral condyle. Repeated measures of analysis of variance (ANOVA) were performed to compare the varus angle among each step, and a post hoc analysis by paired t-test was utilized to compare the parameters between baseline and each step. The varus alignment with valgus stress at extension and 90 degrees of flexion (mean: 6.0 ± 3.6 and 5.2 ± 3.9 degrees of varus, respectively) was significantly corrected to a near-neutral mechanical axis (mean: 0.9 ± 2.4 and 1.4 ± 4.2 degrees of varus, respectively) after peripheral osteophyte resection (p < 0.01, both). In many cases, varus deformity of arthritic knees could be corrected to near-neutral HKA angle by applying manual valgus stress after complete peripheral osteophyte resection. These procedures could facilitate soft tissue balancing in TKA, minimizing the risk of overrelease of the medial soft tissues.

The main surgical requirements for restoring optimal function in total knee arthroplasty (TKA) are an accurate bone cut to achieve alignments and soft tissue balancing throughout flexion.1–5 Balancing has been described as equal and rectangular gaps between the resected bone surfaces in both extension and flexion, implying that the lateral and medial soft tissues maintain equal tensions. Incorrect soft tissue balancing can result in several complications, including instability, abnormal polyethylene wear, aseptic loosening, altered patellofemoral biomechanics, and pain.6,7 Although the standard of care is to balance the gaps symmetrically in both flexion and extension, and multiple techniques have

been described to achieve this surgical objective, there is no consensus on the ideal ligament balancing technique. Recently, it has been suggested that knee varus deformity can be classified as correctable or fixed. In fixed varus deformity, the coronal alignment of the knee cannot be corrected to neutral in preoperative stress radiographs (Fig. 1). Correction of medial soft tissue tightness in severe varus osteoarthritis (OA) may require extensive medial soft tissue release to balance the knee at the time of TKA which is generally performed after femoral and tibial bone cuts. Occasionally, the release of the superficial medial collateral ligament (MCL) from the proximal medial aspect of the tibia with or without the release of the pes anserinus insertion is also required. Unfortunately, this can lead to overrelease of the superficial MCL, hematoma formation, knee joint line elevation, instability, and the need for constrained TKA implants. If the severe varus alignment was to be corrected with valgus manual stress to a near-neutral mechanical axis before bone cuts, it could facilitate the achievement of adequate soft tissue balancing without the need for any additional soft tissue work. Bellemans et al reported that knees with <10 degrees of varus deformity were easily correctable to neutral at extension after correction of the extrinsic factors in their navigation-assisted TKA study. In their study, the correction of preoperative varus deformity was investigated by interposing a specially developed intercalary shim between the medial compartment defects. To elucidate if removal of the extrinsic factors could correct fixed varus deformity both at extension and 90 degrees of knee flexion in the Asian population, uniform subperiosteal release from the medial aspect of tibia and the removal of peripheral osteophytes formed at medial joint space were sequentially performed before any bone cuts in navigation-assisted TKA for the varus OA knee. Instead of interposing a specially developed device to fill the cartilage and bone defect in the medial compartment, manual valgus stress was applied both at knee extension and 90 degrees of flexion, and the hip–knee–ankle (HKA) angle of the knee was recorded using the computer navigation. This study aimed to determine the contribution of uniform release of soft tissue attachment to expose peripheral osteophytes and osteophyte removal to the magnitude of the passive mechanical axis of extension and flexion in preparation for a TKA, using an image-free computer navigation system. Our hypothesis was that severe preoperative varus alignment could be corrected to a near-neutral mechanical axis before bone cuts after uniform release of the deep MCL and complete removal of peripheral osteophytes during TKA in varus OA.

Materials and Methods

Ninety consecutive patients undergoing TKA with computer-assisted navigation for varus knee arthritis from August 2015 to November 2017 were included in this study. Inclusion criteria were varus OA knees with a Kellgren–Lawrence arthritis classification of 3 degrees or more. Exclusion criteria were patients with rheumatoid arthritis (RA) and patients with any history of surgery on the affected leg. All patients were informed regarding the procedure and provided consent for participation in the study and the publication of their data. The institutional review board approved this study. The patient population was composed of 72 (80%) women and 18 (20%) men, with a mean age of 76.7 (range: 63–96) years. The degree of arthritis in the operated knees was classified using the Kellgren–Lawrence arthritis classification based on preoperative standing anteroposterior radiographs. All patients underwent full-leg standing anteroposterior radiographs preoperatively to analyze the HKA angle (Table 1). They were under the care of three experienced surgeons (T. N., H.M., and N.N.) who use computer navigation routinely in their standard TKA practice. The knee navigation system (Ortho Map Precision Knee Navigation Software ver4.0, Stryker, Mahwah, NJ) was used and is based on a principle of hip, knee, and ankle center acquisition via kinematic and anatomical landmark registration processes. After knee exposure, using the medial parapatellar or midvastus approach, active patient trackers were fixed
onto the femur and tibia with two bicortical anchoring pins on each bone. Surgical exposure of the joint was performed to allow the patient’s anatomy to be registered according to standard procedure. After the registration of anatomical landmarks owing to the standard navigation workflows, coronal plane alignment represented by the femorotibial mechanical angle was recorded in both extension and 90 degrees of flexion, both in the neutral position (no applied stress) and at maximum valgus stress.

Initially, no ligamentous releases or osteophyte removals were performed, and the value was documented as the baseline HKA angle (step 0). Thereafter, the following procedures were performed sequentially: step 1, sectioning of the anterior cruciate ligament (ACL) if it was present (if the ACL was torn out due to friction with osteophytes at the exit of the femoral notch, this step was skipped); step 2, elevation of a periosteal sleeve down to approximately 5 mm distal to the joint line including part of deep MCL fibers from the medial aspect of the tibia; and step 3, complete removal of peripheral osteophytes from the medial and posteromedial aspect of the proximal tibia and distal medial femoral condyle. All reachable osteophytes were carefully removed, and the tibia was subluxated anteriorly while applying maximum external rotation torque to the tibia to provide access to the osteophyte built on the periphery of the posteromedial corner of the medial tibial plateau (Fig. 2). The femorotibial mechanical angle with maximum manual valgus stress was recorded at each step on the computer navigation system, and the angle in neutral position was recorded at step 0 and step 3. Moreover, the femorotibial mechanical angle in neutral position after implantation was recorded. All measurements were performed by surgeons with high-volume experience in TKA. Data for all patients were extracted from these navigation files and were used to quantify the effect of each step on varus alignment of the knee.

### Statistical Analysis

All statistical analyses were performed using SPSS version 21 (IBM Corp, Armonk, NY). Repeated measures of analysis of variance (ANOVA) were performed to compare the varus angle among each step, and a post hoc analysis by paired t-test was utilized to compare the parameters between baseline and each step. Statistical significance was defined as $p < 0.05$.

### Results

The mean baseline HKA angle recorded in the neutral position was $10.1 \pm 4.2$ degrees of varus (range: $4.0$ to $20.5$ degrees of varus) at extension and $7.2 \pm 3.5$ degrees of varus (range: $0.5$ to $15.5$ degrees of varus) at 90 degrees of flexion. At step 3, the mean HKA angle recorded in the neutral position was $9.5 \pm 3.9$ degrees of varus (range: $2.0$ to $19.5$ degrees of varus) at extension and $6.0 \pm 3.8$ degrees of varus (range: $0.0$ to $16.0$ degrees of varus) at 90 degrees of flexion. The mean baseline femorotibial mechanical axis recorded with manual valgus stress was $6.0 \pm 3.6$ degrees of varus (range: $-1.0$ to $20.5$ degrees of varus) at extension and $5.2 \pm 3.9$ degrees of varus (range: $-2.0$ to $15.5$ degrees of varus) at 90 degrees of flexion. At step 3, the alignment with valgus stress at extension and 90 degrees of flexion was $5.4 \pm 3.2$ and $4.9 \pm 3.9$ degrees of varus, respectively. At step 2, the alignment with valgus stress at extension and 90 degrees of flexion was $4.7 \pm 3.2$ and $3.9 \pm 4.0$ degrees of varus, respectively.

The mean passive varus alignment with valgus stress was corrected to $1.0 \pm 2.5$ degrees of varus (range: $-4.5$ to $10.0$ degrees of varus) at extension and $1.4 \pm 4.2$ degrees of varus (range: $-10.5$ to $12.5$ degrees of varus) at 90 degrees of flexion after complete resection of the peripheral osteophytes ($p < 0.01$, both vs. baseline; Fig. 3). The passive mechanical axis with valgus stress in knee extension was corrected to $<3$ degrees of varus in 84.4% of cases in extension and 70% of cases in 90 degrees of knee flexion (Fig. 4). The mean HKA angle in the neutral position right after implantation was $0.8 \pm 1.2$ degrees in

extension and 0.5 ± 1.4 degrees in flexion. 96.7% of cases were within 3 degrees of varus and valgus (►Fig. 5).

**Discussion**

The most important finding of this study was that even if it was fixed varus deformity, it could be corrected to a near-neutral HKA angle while applying manual valgus stress, not after subperiosteal elevation of the medial tibial plateau but after complete resection of osteophytes at both the medial and postero-medial edges of the tibial plateau and distal medial femoral condyle before any bone resections during TKA for varus OA. In the current study, medial release and osteophyte removal were performed in the same sequential manner, and the HKA angle of the knee was evaluated objectively with the assistance of the image-free navigation system.22 Based on the results from the sequence of the procedures, resection of the peripheral osteophytes, which tents up the deep and superficial MCL or postero-medial capsule, seems critical to the correction of the fixed varus deformity. These results are in accordance with those in the study by Bellemans et al wherein knees with <10 degrees of varus deformity were easily corrected to neutral after the correction of the extrinsic factors that could cause medial tightness.21

Fixed varus deformity of the knee is associated with bone loss in the tibia and medial femoral condyle, leading to severe varus malalignment secondary to contracture of the medial soft tissue structures. Recently, Thienpont and Parvizi proposed a new classification for the varus knee that allows for a better definition of varus deformity.13 According to their classification, varus deformity can either be intra-articular or extra-articular, and intra-articular deformities can be further classified into correctable or fixed. In our current case series, the passive HKA angle recorded in manual valgus stress after the initial registration was corrected to <3 degrees of varus in 20 knees (22.2%) and was classified as correctable varus deformity. Therefore, many TKA cases in this study presented with fixed varus deformity that needed to be corrected intraoperatively. From an unbalanced state, balancing can be achieved in different ways, including soft tissue release, making small modifications to bone cuts, and changing component sizes. Soft tissue release is the most
common procedure and can be easily performed, although it is less quantitative. Moreover, the procedure requires some experience to be safely performed and is accompanied by the risk of instability. A biomechanical study on cadaveric specimens showed great variability in elongation and failure of the MCL after pie-crusting technique. However, peripheral osteophyte resection is a relatively simple surgical procedure and can be routinely performed even by less experienced surgeons. Here, the passive mechanical axis with valgus stress in knee extension was corrected to <3 degrees of varus in 84.4% of cases in extension and 70% of cases in 90 degrees of knee flexion after complete removal of peripheral osteophytes. Additionally, the final mechanical axis of the knee after implantation was achieved within 3 degrees of varus and valgus in 96.7% of the cases. Hence, we recommend peripheral osteophyte removal initially from both the medial femoral condyle and medial aspect of the tibia before any bone cut as one effective method. This method allows us to understand the soft tissue balance of each patient at the beginning of the procedure, and as a result, it achieves good lower limb alignment in TKA. Once the tightness of medial soft tissue envelop is normalized after these procedures in TKA for varus OA, an appropriate soft tissue balance could relatively easily be achieved without the need for any additional soft tissue work in many cases. It also leads to the preservation of attachment and midsubstance fibers of superficial MCL and the attachments of pes anserinus and semimembranosus, thereby contributing to a well-functioning pain-free knee joint, without the risk of medial soft tissue overrelease.

The sequential procedures performed in this study were not specially designed protocols, but rather the regular workflows used in both cruciate-retaining and posterior-stabilized TKA implantation. After the arthrotomy was performed, the ACL was initially sectioned, while the posterior cruciate ligament was untouched. To subluxate the tibia anteriorly, minimum subperiosteal elevation of deep MCL fibers and the joint capsule from the medial and posteromedial aspects of the tibia was inevitable. The deep MCL was minimally liberated from the underlying osteophytes on the medial tibia. All reachable osteophytes on the medial femur and tibia were carefully removed. Although osteophyte removal from the femur is not challenging, care was taken not to damage the insertion of the superficial MCL at the medial epicondyle. The removal of the osteophytes from the posteromedial aspects of the tibia was performed with the tibia subluxated at maximum external rotation, and care was taken not to damage the semimembranosus insertion.

Limitations

Our study has some limitations inherent in the measurement techniques used. Manual stress testing was performed to assess mediolateral laxity, and despite being performed by experienced surgeons, some degree of variability in the forces exerted during testing cannot be excluded. Moreover, all measurements were to be performed with the knee in full extension (0 degrees of flexion); however, this was not possible in all cases. Cases with flexion contractures were analyzed with the knees in the fully extended position and not at 0 degrees of flexion. However, the use of modern navigation may enable the intraoperative quantification of mediolateral laxity of the knee more accurately and reproducibly compared to any other available alternative. Although the proportion of correctable varus knees after resection of the osteophytes was shown in this study, the relationship between the correction of fixed varus deformity and preoperative varus deformity remains unclear. Further study will be needed to clarify whether fixed varus deformity is corrected or uncorrected depending on the preoperative varus deformity.

Conclusion

Our study demonstrated that varus contracture of arthritic knees could be corrected to near-neutral mechanical axis after complete resection of the peripheral osteophytes in many cases. These procedures may facilitate soft tissue balancing in TKA, while decreasing the need for additional soft tissue work and minimizing the risk of overrelease of the medial soft tissues as a result.
