Introduction

Knee pain is the second most prevailing disorder of knee and patellofemoral pain (PFP) being considered one of the most common forms of knee pain, with incidence ranging between 15 and 45%. PFP is described as nontraumatic diffuse anterior knee pain (AKP) during load bearing activities of the joint such as squatting, running, climbing, and descending stairs. The degeneration of cartilage can quickly lead to tracking issues of the patella and, if left untreated, can often lead to osteoarthritis. There is no descriptive treatment of chondromalacia patella (CMP) due to poor regenerative properties and complex physiology of cartilage. Patellofemoral joint is a part of the knee joint and ironically even knowing the high incidence of PF arthritis and morbidity in middle aged patients, the literature on the understanding of PF factors is scarce and treatment is neither promising nor clear making it one of the tangled topic in today’s orthopaedics.

There is very limited research on correlation of stage of CMP on severity of anterior knee pain and resultant functional morbidity. To our knowledge, this is the first study which has taken into account comprehensively the clinical
Materials and Methods

This was a single-center, prospective, cross-sectional study conducted at a high-volume tertiary center in North India after obtaining ethical approval from the institutional ethical committee. We examined middle aged patients in the orthopaedic outpatient department (OPD) with anterior knee pain who had undergone clinical and magnetic resonance imaging (MRI) examination of the knee and first 50 patients who were diagnosed with late/advanced CMP (grades III and IV, i.e., cartilage loss) constituted group I and 30 patients as (group II) with early CMP (grades I and II, i.e., no cartilage loss). Written informed consent was obtained from all patients. Patients with anterior knee pain for longer than a month and worsening of the anterior knee pain, with at least one of the following activities, were included in the study: climbing or descending stairs, squatting, jumping, and prolonged sitting. The study exclusion criteria were a history of a major trauma, history of past lower extremity surgery and/or fracture, presence of neuromuscular disease, inflammatory rheumatic disease, epilepsy, dementia, pregnancy, history of past lower extremity surgery and/or fracture, presence of neuromuscular disease, inflammatory rheumatic disease, epilepsy, dementia, pregnancy, history of any of the conditions listed above.

In addition to anterior knee pain, complaints, including swelling, feeling of knee giving way, stiffness, locking at the knee, clicking noise during movements of the knee, crepitation, pain triggered by prolonged sitting, step-step limping, sliding knee cap, and difficulty in squatting, were recorded. Patients’ knee physical examination findings, Kujala’s PF scoring system (KPSS), and functional index questionnaire were obtained from the outpatient clinic records. The Q angle was measured by two vectors extending from the anterior mid-patella to the anterior superior iliac spine (ASIS) and tibial tuberosity with knee in 15-degree flexion. The center of the goniometer was placed at the midpoint of the patella. One arm of the goniometer was aligned with the string leading to the anterior superior iliac spine, and the other arm of the goniometer was aligned with the tibial tubercle. Dedicated knee MRI images were evaluated by a radiologist for staging of chondromalacia and PF indexes. All MRI scans were performed on the 1.5 T Magnetom Avanto Siemens MRI and with patient in supine position with their knees 15-degree flexion. Five different measurements were performed in all patients’ knee MRI images as follows:

1. Trochlear sulcus angle: it is the angle between the two lines that connects the deepest point of the trochlea to the anterior medial and lateral femoral condyles measured on axial scans (Fig. 1), a trochlear angle greater than 144 degrees was evaluated as trochlear hypoplasia.

2. Trochlear sulcus depth: it is the distance between the deepest point of the trochlear sulcus and the line connecting medial and lateral femoral condyles. A sulcus depth lower than 5 mm was accepted as hypoplasia and a depth lower than 3 mm was accepted as a sign of dysplasia.

3. Insall–Salvati index (patellar tendon length/the longest diagonal diameter of patella): it is the ratio of patellar tendon length to the longest diagonal diameter of patella (Fig. 2). It was measured using the sagittal section where maximum length of patella was visualized (often the section where anterior cruciate ligament can be visualized). Patellar tendon length was divided by the longest diagonal diameter to calculate the Insall–Salvati index. Values below 1.1 were accepted as patella baja, and values above 1.3 were accepted as patella alta.

4. Lateral patellofemoral angle: it is the angle between the line connecting anterior medial and lateral femoral condyles and the line drawn tangential to the lateral patellar facet. This angle is used for the evaluation of patellar tilt and is measured using the axial section corresponding to the middle point of the patella at the sagittal plane. This angle usually opens laterally, so any medial angulation or an angle lower than 8 degrees to the lateral side was evaluated as a sign of abnormal tilt.

5. Patellar translation: it is measured to assess patellar subluxation. It is the distance between the vertical line passing from the anterior of medial femoral condyle and the vertical line passing from the medial most border of the patella measured on the axial planes. A >2-mm sliding toward the lateral side was evaluated as subluxation.

Additionally, in all patients, the CMP grading/stage was determined from the MRI images. Patients were categorized into early and late CMP groups based on four stages on the MRI staging system that was modified Outerbridge’s arthroscopy staging system. In case, cartilage injuries in the medial and patellar facet were at different stages, the highest stage was considered for categorizing the patient.

Finally, we evaluated respective correlation of the advanced CMP group (stages 3 and 4) and early CMP group with PF indexes, patellar morphology (Wiberg’s classification), Q angle, and patellar position in patients with anterior knee pain.
To test the interobserver reliability, another radiologist performed quantitative and semiquantitative measurements of randomly selected 50 knees among 80 knees.

Statistical Analysis
Statistical analysis will be performed using the Statistical Package for Social Sciences (SPSS) software version 16 (SPSS Inc., Chicago, Illinois, United States). To compare the categorical data in terms of other categorical properties, Chi-square and Fisher’s exact tests were used. Any two groups were compared with regard to measurement values using the Mann–Whitney U-test. A p-value of <0.05 was accepted as statistically significant.

Results
Only a small fraction of patients showed type-A and -C morphologies of patella as shown in Figs. 4 and 5. Trochlear morphology results came out to be significant with higher sulcus angle (153 degrees) and shallow trochlear sulcus (3.9 mm) as shown in Figs. 1 and 6. We observed higher
number of patients in patella alta:patella baja in late CMP group but the results are not significant. Clinical scores were significantly better in early CMP group as compared with late CMP group (Fig. 7).

Discussion

In previous studies, the overall sensitivity and specificity of MRI in the diagnosis of patellar cartilage defects ranged between 83 and 97%. Only 10% of CMP patients require surgery, so it is very difficult to justify every doubtful CMP patient to prepare for surgery.16

A high Q-angle leads to valgus stress with excessive pressure on PF articulation, consequently resulting in CMP. Most of the western studies suggest that there is a significant association between AKP and Q-angle17-19 and there are multiple studies to counter the same.18,20 So, the validity of Q-angle is dubious. In our study, the average Q-angle in advanced and early CMP group was 17.1 and 13.2 degrees favoring association between Q-angle and anterior knee pain but the result was statistically nonsignificant (as shown in Table 1). We believe that Q-angle is an important parameter which can have a significant association with anterior knee pain but the cause of indecisive results could be because of its measurement bias, dynamic character, and multifactorial association.

To evaluate the relationship between the stage of chondromalacia and severity of pain experienced by patients, PF severity scale scores were used.5-7 Patients in the advanced-stage CMP group had higher scores. To our knowledge, there are only couple of studies in literature which analyzed the relationship between pain intensity and disease progression.6,21,22 In literature, only one study prospectively followed-up clinical symptoms in patients who were categorized based on trochlear and patellar cartilage injury in arthroscopy and found greater functional limitation and more subjective complaints among patients with more severe cartilage injury.6 Our study showed a significant difference in the clinical scores of late and early CMP groups with Kujala’s functional score lower (61 as compared with 78 in early CMP) and PF pain score higher in the advanced CMP group (43 in comparison to 25 in early CMP shown in Table 2). Our results equate with Aysin et al who observed that those with more advanced CMP reported higher pain severity and lower knee function compared with those with early CMP, but they found no difference in the MRI measurements of two groups.21

There is plenty of research work done on trochlear morphology and PF pathology with contrasting results. The three-dimensional shape of the femoral trochlea is becoming the center of consideration in determining CMP. According to Ali et al, the trochlear morphology plays a key role in PF pathology and should always be taken into account while taking PF parameters. Our study favored multiple previous studies showing significant MRI results of lower trochlear depth and higher TSA are associated with higher cartilage defects (Table 3 and Fig. 8). This finding supports our assumption which proposes that knees with flattened lateral trochlea are more likely to face CMP and we can identify patients at risk of developing CMP with higher TSA.

Patellar tilt can be assessed by lateral femoral angle which didn't show any association with the CMP in our study, supporting by the study of Aysin et al. Contrary to our results, Yang et al and Tuna et al found correlation between lateral femoral angle and CMP with smaller lateral PF angle or medial opening of angle that is associated with higher probability of cartilage defect.

The literature is muddled with multiple knee examination tests and we know that there is no single best clinical test to predict CMP. The low sensitivity and predictive value of Clark’s sign as shown by Doberstein et al were also strengthened in our study than 50% of advanced CMP patient had positive Clark’s sign. So, we are of this opinion that combining clinical test with clinical scores of KPSS or PFP scale (PFPS) can increase the predictability rate of CMP and may help to formulate a criteria to diagnose it more precisely. However, to verify this presumption, there is a need for extensive research with large series showing substantial data.

Articular cartilage defects (ACD) in the PF region are more common with various dysplastic shapes of the patella. However, a small number of investigations have revealed correlations between the shape of the patella and ACD in the PF region. Wiberg himself stated that type-A (I) and -B (II) shapes of patella are less destined to ACD in the PF region. Our study supported Gudas et al and Wiberg’s classification system observing type II as most common variant and type C most closely associated with advanced CMP. Gudas et al observed type-II patella as most common variant and also concluded that the shape of the patella is an important anatomic parameter which may reflect the development of articular cartilage defects in the PF region. So, it can be anticipated that type-C (III) morphology can have a progressive course to CMP which further can be halted by proactive measures in the form chondroprotective drugs and strict adherence to “do’s and don’ts” regimen for the knee care.
Insall–Salvati ratio has been the matter of debate as a possible risk factor for CMP. Limited studies found an association between patella alta and CMP postulating that patella alta contributes to maltracking and PF mismatch. Other studies have shown no significant correlation between Insall–Salvati ratio and CMP. Dowd and Bentley rather found association between patella alta and patellar instability but failed to find any correlation with CMP. In concordance with these findings, our study did not show any significant interconnection between the presence of CMP and Insall–Salvati ratio despite having higher ratio of patella alta to patella baja in advanced chondromalacia group.

Limitations
This study includes following limitations: static Q angle, non-feasibility of standing position for MRI, medium cohort size, no follow-up, and no arthroscopy correlation.

Future Considerations
Further studies should have a longer follow-up with larger group specifically focusing on trochlear and patellar morphology and assessment of progression in CMP.

Conclusion
A holistic approach is required to interpret the multifac torial association of CMP. Our study concludes that a combination of Q angle, clinical examination, and PF scores can be used in the preliminary criteria to isolate CMP patients. These patients further can be directed for detailed radiological imaging of trochlear and patellar morphology to delineate underlying pathology, severity, and management. Furthermore, radiological criteria can be generated to predict progression of early to late CMP and to assess patients at risk of developing CMP. Lateral PF angle and Insall–Salvati ratio add little to the understanding of CMP pathology and may be skipped in routine PF assessment.

Ethical Approval
This study was approved by Ethics Committee and the ethical approval number is GGS/IEC/19/19.

Financial Support and Sponsorship
None.

Conflicts of Interest
There are no conflicts of interest.

Acknowledgment
