Abstract

Introduction Pituitary adenomas are a common intracranial pathology with an incidence of 15 to 20% in the population while cerebral aneurysms are less common with a prevalence of 1:50 patients. The incidence of aneurysms in patients with pituitary adenoma has been estimated at 2.3 to 5.4% of patients; however, this remains unclear. Equally, the management of concomitant lesions lacks significant understanding.

Methods A case report is presented of a concomitant cerebral aneurysm and pituitary adenoma managed by minimally invasive endovascular and endoscopic methods, respectively. A systematic review of the literature for terms “pituitary adenoma” and “aneurysm” yielded 494 studies that were narrowed to 19 relevant articles.

Results We report a case of a 67-year-old patient with an enlarging pituitary macroadenoma, cavernous carotid aneurysm, and unilateral carotid occlusion. After successful treatment of the aneurysm by a pipeline flow diverter, the pituitary adenoma was surgically resected by an endoscopic transsphenoidal approach.

Conclusion The use of a pipeline flow diverter and endonasal approach was feasible in the treatment of our patient. This is the first report to our knowledge of the use of pipeline flow diversion in the management of a cavernous carotid aneurysm prior to pituitary adenoma treatment.

Introduction

Pituitary adenomas are the third most common intracranial tumors in adults with an estimated prevalence of approximately 15 to 20% of the population.¹ Although pituitary

adenomas are overwhelmingly benign, they can still confer significant health burden due to visual loss and endocrine dysfunction. Management of pituitary adenomas remains complex due to the heterogeneity of tumor types with multiple guidelines and consensus statements currently

being available; however, surgical resection remains the mainstay of treatment for the majority of symptomatic pituitary adenomas.²⁻⁴

Intracerebral aneurysms show a prevalence of 1:50 for unruptured aneurysms; however, the presence of coincident pituitary adenomas and cerebral aneurysms is rare.⁵ Retrospective studies demonstrate an incidence of intracranial aneurysm in patients with a pituitary adenoma of 2.3 to 5.4%,^{6,7} suggesting a purely coincidental relationship.

The combination of a cavernous sinus aneurysm embedded within a pituitary adenoma is even rarer and the approach for treatment is controversial. In this report, we detail the management of a patient with a nonfunctioning pituitary macroadenoma and an embedded cavernous carotid aneurysm. A systematic review of the literature was performed showing 20 prior reports of pituitary adenomas with associated aneurysms of the cavernous sinus (►Table 1). We also discuss the integration of modern endovascular therapy and propose a novel treatment strategy.

Literature Review

A systematic literature review was performed on PubMed with search terms “pituitary adenoma” and “aneurysm.” A total of 494 studies were identified and after review of study titles and abstracts, the number was narrowed down to 20 articles after removing duplicates, studies not in English, and nonclinical studies (►Fig. 1). Patients were included if they demonstrated concomitantly treated pituitary adenomas and intracerebral aneurysms of the cavernous sinus. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines were used in drafting this manuscript.

Case Report

The patient was an asymptomatic 67-year-old male presenting with a nonfunctional pituitary macroadenoma (17 mm × 16 mm × 13 mm) and an associated left cavernous carotid artery aneurysm protruding into the left superior aspect of the tumor discovered incidentally during evaluation for headaches (►Fig. 2). The pituitary adenoma showed superior displacement of the normal pituitary gland and minimal suprasellar extension without abutment of the optic chiasm. Vascular imaging showed a left cavernous carotid artery aneurysm (3.7 mm × 3.4 mm), complete right internal carotid artery (ICA) occlusion, and a small anterior communicating artery (ACOM) aneurysm.

The macroadenoma and aneurysm were followed closely with serial imaging for 6 years until slow progressive growth of the pituitary adenoma demonstrated compression of the optic chiasm. Ophthalmologic evaluation revealed no visual deficits. After a multidisciplinary discussion, a recommendation for initial repair of the aneurysm followed by delayed tumor treatment was made. The patient proceeded initially with attempted coil embolization which could not be completed due to aneurysm anatomy. Subsequently, a

5 mm × 18 mm pipeline flex flow diverter was placed. The patient was maintained on dual antiplatelet therapy and the aneurysm showed complete radiographic occlusion 6 months later (►Fig. 3). Repeat magnetic resonance (MR) imaging showed progression of the macroadenoma (21 mm × 19 mm × 22 mm) with increasing optic tract compression. Unfortunately, before tumor surgery could be performed, the patient suffered a minor cerebrovascular accident (CVA) which was treated with resumption of dual antiplatelet treatment for an additional 6 months and continued on maintenance aspirin.

For the pituitary adenoma resection, an endoscopic transphenoidal approach was performed using the previously described “1.5 approach” that involves a full unilateral sphenoidotomy and smaller contralateral sphenoidotomy with preservation of bilateral sphenopalatine artery pedicles to the nasal septum.⁸ During surgery, extreme caution was taken in the left lateral region of the sella where the aneurysm and only patent carotid artery were located. A gross total resection of the tumor was accomplished. The patient was discharged on postoperative day 1 and aspirin was reinitiated 3 days postsurgery without complication.

Discussion

The presence of a pituitary macroadenoma with an embedded cavernous sinus aneurysm is an exceptionally rare phenomenon which requires special considerations.^{6,9} Currently available guidelines²⁻⁴ do not make specific recommendations on this rare situation. The incorporation of endovascular treatments in the management of pituitary tumors and aneurysms has had limited exploration.

We conducted a review of the literature and analyzed all case reports discussing the phenomenon of a cavernous sinus aneurysm embedded within a pituitary adenoma (►Fig. 1). A total of 20 studies described pituitary adenomas in direct contact with cavernous sinus aneurysms (►Table 1). Regarding aneurysm treatment among the 20 studies, 14 involved endovascular approaches, 5 involved open approaches, and 1 case showed a patient fatality prior to treatment. For adenoma treatment, 4 involved transcranial approaches, 11 involved endonasal approaches, 4 involved medical management, and 1 patient had a fatality prior to treatment (►Fig. 1). To our knowledge, our case represents the first case of initial aneurysm treatment with pipeline flow diversion prior to adenoma treatment. The use of the pipeline aided the treatment of an aneurysm in an otherwise difficult location to treat. Certainly, the use of a pipeline stent and need for antiplatelet medication complicate the timing for adenoma resection; however, as most adenomas are slow growing, the urgency of tumor treatment is less significant.

Several cases of ruptured intracranial carotid artery aneurysms embedded within adenomas causing subarachnoid hemorrhage have been reported.¹⁰ Additionally, aneurysms in the posterior circulation have also been described which may confer increased surgical morbidity during pituitary surgery.¹¹ Cavernous carotid artery aneurysms located proximal to the distal dural ring present a decreased risk for

rupture-associated morbidity and mortality due to their extradural origin and are therefore less commonly treated surgically or endovascularly.⁵ Rupture of aneurysms extending within pituitary adenomas, however, may present as pituitary apoplexy with visual, cranial nerve, and endocrine dysfunction.¹² Additionally, cavernous aneurysms located within pituitary adenomas carry risk for catastrophic rupture during surgical resection of these tumors. While the mortality rate for aneurysm rupture during pituitary surgery is not known, a 14% mortality rate after carotid artery injury during transsphenoidal surgery has been reported with a 24% rate of significant neurological disability.¹³ As such, the decision to proceed with surgical intervention for pituitary adenomas in these rare cases requires either a preoperative or concomitant strategy for treating the aneurysm.

Fortunately, management strategies for the treatment of cerebral aneurysms have greatly expanded and improved over the last several decades with the decision to coil, flow-divert, or clip a cerebral aneurysm partially depending on the angiographic features of the aneurysm and ability to tolerate single or dual antiplatelet agents to prevent thromboembolic complications. Several cases of simultaneous open

transcranial or combined transcranial and endoscopic clip ligation management of intracranial aneurysm rupture and pituitary adenoma resection have been reported in the setting of subarachnoid hemorrhage.¹⁴ Although open surgical treatment of a carotid cavernous aneurysm and pituitary adenoma has been described previously in the literature,^{15,16} this method has been replaced by modern endovascular techniques. Endovascular treatments are generally associated with lower medical comorbidity than open treatment but may require the use of single or dual antiplatelet agents that would delay the timing of pituitary adenoma treatment, especially with the use of flow diversion.¹⁷

Modern approaches for the treatment of pituitary adenomas and carotid aneurysms have incorporated the use of endovascular treatment to secure aneurysms before tumor surgery.¹⁸ Coil embolization typically does not require the postoperative use of antiplatelet agents and may be considered the preferred option for securing the aneurysm. Endovascular coiling, however, is highly dependent on the aneurysm morphology and may result in incomplete aneurysm obliteration or aneurysm recurrence. Alternatively, for aneurysms with wide necks or not amenable to direct

Fig. 2 Preoperative MRI and angiogram views of concomitant pituitary adenoma and internal carotid artery aneurysm. Preoperative (A) coronal and (B) sagittal T1 contrast enhanced imaging demonstrates a pituitary macroadenoma with expansion of the sella (arrow). (C) Anteroposterior and (D) lateral cerebral angiogram views demonstrate a medial projecting cavernous segment aneurysm.

coiling, stent-assisted coiling or flow-diversion strategies may be utilized. Flow diverters promote aneurysm occlusion through a process of endoluminal reconstruction of the parent artery and by redirecting blood flow away from the aneurysm sac. Review of patients at our institution treated with the pipeline embolization device demonstrated a complete aneurysm occlusion rate of 86% which was significantly higher than that achieved with coiling (41%).¹⁹ The thrombogenicity of flow diversion stents, however, requires the use of single- or dual-antiplatelet therapy to reduce the risks of thromboembolic complications. Overall, thromboembolic events have been observed in approximately 6% of patients with higher rates of complications occurring in patients treated with aspirin and clopidogrel therapy for less than 6 months.²⁰ Therefore, the use of aneurysm obliteration via flow diversion should occur at least 6 months prior to any planned surgical intervention for the pituitary adenoma and may be best reserved for asymptomatic patients without optic apparatus compression or progressively enlarging adenomas where intervention may be safely delayed.

Many cavernous sinus aneurysms do not present with symptoms, though some may result in cranial nerve palsies due to their proximity in the cavernous sinus. According to Stiebel-Kalish et al, the most common presenting symptoms are diplopia (65%), pain (59%), and unilateral headaches (33%).²¹ Less commonly, the aneurysms may rupture, causing carotid-cavernous fistulas or severe epistaxis warranting immediate surgical intervention. In 18 of the 20 cases included in our systematic review, the cavernous aneurysms were found incidentally on imaging workup (— **Table 1**) and

the selection of treatment for these incidental aneurysms will depend on patient risk factors, aneurysm morphology, and tumor behavior including the urgency with which the adenoma must be treated.

In general, the preferred treatment for ruptured or unruptured cavernous aneurysm with a pituitary adenoma would be endovascular coiling. Antiplatelet therapy is generally not required and this intervention has been shown to provide aneurysm protection with low morbidity and facilitate trans-sphenoidal resection of the adenoma.^{10,18,22–26} The rare cases of aneurysms are not amenable to coiling for which urgent decompression of the adenoma is necessary, typically due to macroadenomas with suprasellar extension and vision loss or pituitary apoplexy, a transcranial approach with simultaneous tumor resection and clipping of the aneurysm may be indicated.^{15,16,27,28} While endoscopic endonasal intracranial clipping of cavernous carotid aneurysm has been reported and is technically feasible, simultaneous endonasal pituitary adenoma resection and aneurysm has not been performed to the best of our knowledge.²⁹ Additionally, a recent review of endonasal aneurysm clipping demonstrated significantly higher rates of complications compared with open clipping and endovascular management.³⁰ In our opinion, consideration of endoscopic endonasal clipping of an aneurysm during pituitary adenoma resection is best reserved for emergency management of inadvertent intraoperative aneurysmal rupture encountered during the tumor resection. In the event that an unruptured aneurysm is unexpectedly discovered during pituitary adenoma resection, due to the potential for catastrophic

hemorrhagic complications, we recommend that subtotal tumor resection to be performed without perturbation of the aneurysm. Subsequent definitive aneurysm therapy may then be pursued followed by delayed reintervention for the adenoma if clinically indicated.

As an additional point of consideration, surgical reconstruction of the skull base defect after adenoma resection by use of a nasoseptal flap may warranted to provide long-term protection of the aneurysm from inadvertent injury from subsequent interventions, such as nasogastric tube placement or to provide an additional layer of coverage, to the aneurysm wall in cases of stereotactic radiosurgery is anticipated.^{30,31}

Conclusion

This case report and systematic review suggests that concomitant treatment of cerebral aneurysms and pituitary adenomas requires knowledge of up-to-date surgical and endovascular options for each pathology, as well as careful consideration of the timing and sequence of intervention.
