Abstract
Introduction Acromion is essential for stabilizing the shoulder complex. Tumors of the acromion are rare. We report the largest series of acromion tumor and tumor-like lesion.

Materials and Methods A retrospective review of the oncology and radiology database within our tertiary center for orthopaedic oncology was performed to identify all tumors of the acromion over the past 30 years and imaging was reviewed.

Results We identified a total of 31 lesions arising in the acromion and chondrosarcoma was the commonest.

Conclusion One needs to be aware of tumor and tumor-like lesions of acromion.

Introduction
The acromion process is an anatomical structure that is essential in stabilizing the shoulder complex and forms attachments to many important muscles of the shoulder joint. Tumors arising from the acromion process are considered rare and the literature regarding their clinicopathological characteristics, radiological findings, and management is scarce. Due to this, diagnosis is often delayed, resulting in poor patient outcomes.1

Radiographs, computed tomography (CT), and magnetic resonance imaging (MRI) all play a major role in the characterization of these lesions. This study reports the largest case series of isolated tumors of the acromion, and provides a pictorial review to illustrate imaging findings of tumors and tumor-like lesions at this site.

Methodology
A retrospective review of the oncology and radiology database within our tertiary center for orthopaedic oncology was performed to identify all tumors of the acromion over the past 30 years. All available imaging were reviewed by a musculoskeletal radiologist with more than 8 years experience. Patient demographics including age, sex, and tumor type were recorded.

Results
We identified a total of 31 lesions arising in the acromion (►Table 1). The average age was 52 years (range: 12–84 years). There was a female predominance with a female-to-male ratio of 1.6:1 (19 females and 12 males). The majority of the lesions identified within our cohort were malignant constituting 75% (n = 23) of all cases. Benign tumors were found in 19% (n = 6) and nonneoplastic lesions formed 6% of all cases (n = 2) (►Table 2). There was a mixture of benign and malignant lesions in different age groups (especially >30 and <30 years).

The most common isolated malignant tumor identified was chondrosarcoma (n = 7). This was closely followed by plasmacytoma in six cases. All other malignant tumors are

illustrated in Table 2. The most frequent benign tumor encountered within the study was osteochondromas ($n = 3$). Nonneoplastic lesions included total of four cases of osteomyelitis, fibrous dysplasia, and eosinophilic granuloma.

### Discussion

**Anatomy**
The acromion is a large, flat bony anatomical structure that arises from the lateral end of the spine of the scapula and projects anteriorly to articulate with the lateral end of the clavicle. In the adult, it measures $\sim 2.5$ cm in width and is roughly 5 cm long. It serves as an important landmark of the skeletal system, and provides muscle attachments for the deltidoid and trapezius which are essential to the function of the shoulder joint. Lesions arising within the acromion have the potential to disrupt the shoulder complex, leading to severe morbidity due to loss of function.

**Chondrosarcoma**
Chondrosarcomas are malignant tumors that originate from cartilage producing cells (chondrocytes). They are known to be the second most common primary malignant osseous lesions, second to osteosarcoma. The incidence of chondrosarcoma is relatively rare with a reported incidence of $\sim 5\%$. The incidence in the acromion is unknown. They typically arise between the fourth and fifth decades of life and have a slight male predilection. Clinically, chondrosarcomas have

nonspecific symptoms often presenting with a painful palpable lump or local mass effect.\(^4\) Since clinical diagnosis is unreliable, patients suspected of having chondrosarcoma often undergo imaging.

On radiographs, chondrosarcomas demonstrate intraleSIONAL calcification, seen as ring-and-arc chondroid or popcorn-like calcification, with endosteal scalloping and soft tissue extension (\(\sim\)Figs. 1, 2, 3). CT can also be useful to aid in delineating chondrosarcomas. On CT, chondrosarcoma appears with osteolytic destruction, endosteal scalloping, cortical breaching, calcification, and an expansile remodeling component (\(\sim\)Figs. 1, 2, 3).\(^3\)

MRI is the gold standard imaging modality for radiological diagnosis. The nonmineralized portion of the lesion, the soft tissue mass, as well as the surrounding tissues can all be evaluated on MRI. The calcifications appear hypointense on all pulse sequences. The cartilaginous matrix manifests as lobulated high T2 and low T1 signal areas (\(\sim\)Figs. 1 and 2). It is important to note that when the thickness of the cartilage cap is more than 2 cm in mature bone, it is highly suggestive of malignant transformation from an original osteochondroma.

The radiological findings can reflect the pathological appearances of the different distinctive subtype features. High-grade chondrosarcomas are more likely to show variable MR appearance. The typical lobular appearance of the chondroid matrix is often absent in the dedifferentiated chondrosarcoma. Low-grade chondrosarcomas may have fibrovascular septa between lobules of hyaline cartilage and are more difficult to be distinguished from enchondromas.\(^5\) Therefore, an accurate diagnosis based on morphologic feature alone is difficult, and correlation of radiological and clinicopathological features is mandatory.\(^7\)

### Metastasis—Breast and Renal Cell Carcinomas
Skeletal metastasis is very common and considerably more prevalent than primary bone malignancy.\(^6\) The most common metastatic tumors identified within our cohort were secondary to breast and renal cell carcinoma primaries.

Bone metastasis associated with breast and renal cancers is common, and thought to be due to the selective colonization of the tumor toward bone.\(^9\) History and clinical examination are key in ensuring appropriate diagnosis and management. Furthermore, imaging is essential to further confirm diagnosis and aid in management plans.

Radiographs are nonspecific and are mostly useful in the identification of associated pathological fractures. MRI is more conclusive, and features of metastatic breast carcinoma in the acromion process appear as destructive low signal intensity lesion on T1-weighted imaging (T1WI), with no significant fluid signal in the destructive lesion on T2-weighted imaging (T2WI) (\(\text{Figs. 4, 5, 6}\)).

In metastatic renal cell carcinoma, radiographs can demonstrate a more characteristic "soap bubble appearance,” a poorly demarcated osteolytic lesion within the acromion process (\(\text{Fig. 4}\)). MRI is highly sensitive, due to its capability in demonstrating intramedullary metastatic deposits in the early stages of the disease. Signal voids can be seen in these as there is hypervascular metastasis (flow void sign). Moreover, it can be used to assess metastatic spread in the marrow cavity, the extension of tumor disease, and the involvement of other surrounding structures. Bony metastasis involving the scapula is generally treated nonsurgically with radiotherapy playing a critical role in the palliative management of these lesions.\(^10\)

**Multiple Myeloma and Plasmacytoma**

Multiple myeloma (MM) is a plasma cell dyscrasia characterized by the abnormal proliferation of plasma cells and immunoglobulins in the blood that lead to specific end-organ damage. Plasmacytoma is the solitary localized variant of MM.\(^11\) Osseous manifestations of this tumor constitute a very important component of the disease. However, the incidence in the acromion process is not known, and as far as the authors are aware, it has not been reported in the literature.

Radiologically, four types of bone destruction can be caused by MM.\(^12\)

- Type I: solitary plasmacytoma: a single expansile lesion, most common in vertebra and pelvis
- Type II: multiple “punched out” osteolytic lesion
- Type III: disseminated skeletal osteopenia causing diffuse osteoporosis
- Type IV: diffuse osteosclerosis.

The radiographic appearances of MM are nonspecific, and can present as a subtle lytic lesion in the acromion process (\(\text{Figs. 7 and 8}\)).
On CT, features include a large expansile soft tissue mass with cortical breakthrough (Fig. 7). CT imaging is also useful in evaluating pathological fracture risk and provides a platform to perform percutaneous imaging biopsy when required.

MRI is the imaging modality of choice when evaluating this lesion, and is highly sensitive and additionally plays a major diagnostic role in disseminated MM. On T1WI, MM appears as a homogenous isointense signal to the muscle. On T2WI, the lesion appears brighter than normal marrow signifying increased signal intensity. On fat-suppressed T1-weighted sequences, the lesion has increased signal intensity (Fig. 8). On gadolinium postcontrast sequence, myeloma deposits demonstrate contrast enhancement in acromion. On short-tau inversion recovery (STIR), the tumor appears to have high intensity signal. Treatment options vary and depend on stage and progression of disease. In MM, the current recommended treatment is chemotherapy, and bone marrow or peripheral stem cell transplant along with other conservative measures.

**Non-Hodgkin’s Lymphoma**

Primary osseous non-Hodgkin’s lymphoma (NHL) is rare and accounts for 3 to 5% of all primary bone tumors. NHL has many different subtypes, of which diffuse large B cell lymphoma or follicular lymphoma most commonly affects the bone.

Radiographic features of osseous lymphoma are variable and depend on the subtype present. Often, extensive involvement of the bone with a “moth-eaten” destructive appearance is present and the periosteal reaction can show a “lamellated onion peel” or “discontinuous” appearance, associated with poor outcomes. CT plays a role in the staging of the disease, while MRI is the mainstay imaging modality for the diagnosis of lymphoma.

On MRI, T1-weighted pulse sequences are optimal for demonstrating marrow changes, revealing areas of low signal intensity. On T2 images, the peritumoral area and reactive marrow changes generally appear bright. The soft tissue extension is usually disproportionately large in comparison to the cortical destruction (Fig. 9). It has been suggested that this finding occurs due to the spread of the tumor cells from the bone marrow through small vascular channels that run through the cortex into the surrounding soft tissue. Despite imaging proving useful, a biopsy is almost always required to confirm the diagnosis. Treatment of NHL involves a mixture of chemotherapy and immunotherapy agents with aims to reduce the size of the lesion.

**Benign Lesions of the Acromion Process**

Benign lesions of the acromion process are rare and their incidence is not reported in the literature. Benign tumors of the acromion identified within our cohort included osteochondromas and chondroblastoma.

**Osteochondroma**

Osteochondroma is the most common benign bone tumor. It is commonly found in adolescents and children. They can...
be solitary or multiple, the latter often associated with hereditary multiple exostoses syndrome. Osteochondroma of the scapula is found in ~3 to 5% of all osteochondroma cases.\textsuperscript{19} Their incidence in the acromion is unknown, with limited reported cases in the literature.\textsuperscript{20–22} Osteochondromas of the acromion can either present with a noticeable or asymptomatic mass, signs of impingement syndrome,\textsuperscript{20,21} or with secondary complications caused by the tumor including fractures, bony deformity, vascular compromise, neurological sequelae, or bursa formation.\textsuperscript{23} It is important to note that osteochondromas do also have a potential for malignant transformation.\textsuperscript{23,24}

Both radiographs and CT images of osteochondroma may demonstrate a sessile or pedunculated lesion with cortical irregularity, medullary continuity, and a cartilage cap.

MRI is the gold standard imaging modality used to assess the cartilage cap (\textsuperscript{Fig. 10}). Postcontrast MRI may demonstrate the heterogeneous enhancement in the lesion. Treatment options are individualized to patient’s preference, with asymptomatic or minimally symptomatic lesions often undergo surveillance and provided with supportive care. Surgical resection can be considered if there is a risk of an impending fracture or the presence of the other secondary complications described earlier.

**Chondroblastoma**

Chondroblastoma is a rare benign but aggressive cartilaginous neoplasm formed of chondroblasts.\textsuperscript{25} Chondroblastomas are rare and represent less than 1 to 2% of all primary bone tumors. It usually affects adolescents and young adults, with a slight male predominance. The acromion is a very rare site for this tumor to arise with only a few cases reported in the literature.\textsuperscript{26} Chondroblastomas are best demonstrated on MRI appearing as a low to intermediate signal intensity homogenous lesion on T1WI. On T2WI, the lesion demonstrates intermediate to high signal intensity. Moreover, secondary aneurysmal bone cysts can be seen accompanying chondroblastomas in ~20% of cases, classically presenting with the fluid–fluid levels.\textsuperscript{27} On radiographs and CT images, chondroblastomas are characteristically seen as single lucent lesions, with either smooth or lobulated margins, septations, cortical expansion, or a sclerotic rim. CT is particularly useful to define the relationship of the tumor with the surrounding tissues given the destructive nature of the tumor. Management of chondroblastoma includes curettage, marginal resection, and percutaneous radiofrequency ablation.

**Osteomyelitis**

Other lesions we identified within our cohort included infection. These lesions can be distinguished with appropriate clinical history and examination. Patients with osteomyelitis or eosinophilic granuloma of the acromion can present with debilitating symptoms such as pain, sepsis, and loss of function.\textsuperscript{28} Therefore, early diagnosis and management are essential to ensure effective treatment is initiated.

Nonneoplastic lesions can have similar imaging features to that of tumors. Radiographic imaging is usually first line,
but has a low sensitivity and specificity for detecting infection of the bone.\textsuperscript{29} However, it is necessary to exclude other pathologies such as fractures. Late signs (7–10 days) that can be seen on radiographs include destruction of the bone typically manifesting as a focal radiolucent lesion. MRI is the predominant imaging modality for diagnosis of infection, owing to its high sensitivity for detecting edema around the focus of infection. T2-weighted and STIR images may demonstrate high signal intensity in the acromion, subperiosteal fluid, and subacromial bursa fluid. CT may be helpful if a sequestrum is suspected on MRI.

Other lesions of acromion include eosinophilic granuloma and fibrous dysplasia (\textit{\textbf{Fig. 11}}).

\textbf{Conclusion}

Tumors of the acromion are rare. We provide the largest case series of lesions of the acromion and present a comprehensive pictorial review and diagnostic algorithm aimed at aiding radiologists in the diagnosis of these lesions (\textit{\textbf{Fig. 12}}). Majority of acromion tumors are malignant.
