Abstract

Tension pneumocephalus is a rare and life-threatening neurosurgical emergency in the setting of blunt or penetrating head trauma, especially in those with craniofacial fractures, which emergency physicians should be aware about. Early identification and appropriate treatment measures including supine positioning, 100% oxygen via mask, early neurosurgery consultation and, if required, operative intervention are paramount to optimal neurological and survival outcome. Definitive diagnosis requires imaging usually in the form of computed tomography (CT) head and serial monitoring of neurological status, optic nerve sheath diameter measurement and repeat imaging, essential to identify patients who might have features of increased pressure on brain matter, which could lead to adverse neurological and clinical outcomes. We present two cases of tension pneumocephalus with the characteristic Mount Fuji sign on CT head, who were managed nonoperatively with optimal neurological outcome. In patients with severe head or maxillofacial trauma presenting to emergency department, CT should be evaluated for signs of tension pneumocephalus, and such patients need to be closely observed for complications of pressure effect on brain matter to ensure optimal neurological and survival outcomes.

Introduction

Pneumocephalus (also known as pneumatocele) is quite common in the setting of trauma, especially those associated with head injury. In this setting, it can occur either as a result of trauma itself or postsurgical intervention. Tension pneumocephalus, a potentially fatal condition, however, is quite rare and is a treatable emergency. It occurs due to collection of air within the cranial cavity with increased pressure on brain matter along with neurological deterioration.1 There are two theories postulated for the development of tension pneumocephalus, which include the Dandy theory and Horowitz theory. The Dandy theory suggests a ball valve mechanism, leading to one way entry of air through a dural defect, resulting in entry of air into cranial cavity with trapping of air.2 The Horowitz theory suggests an inverted soda bottle effect from loss of cerebrospinal fluid (CSF), resulting in negative pressure in the cranial cavity.3 Posttraumatic tension pneumocephalus reported in literature is mostly associated with severe craniofacial fractures. Early and prompt identification is of utmost importance to avoid adverse neurological outcomes and mortality. Management involves conservative measures, including high-flow oxygen therapy, supine positioning, analgesia, prophylactic antibiotics in...
posttraumatic cases, frequent monitoring of neurological status clinically, and using imaging. Operative management for those not improving or those with symptomatic tension pneumocephalus includes prompt decompression by drilling burr holes, needle aspiration, and craniotomy or ventriculostomy. In addition, the dural defect should be identified and sealed off to prevent further worsening or recurrent pneumocephalus. Here, we present two patients who presented with trauma-associated tension pneumocephalus who were successfully managed nonoperatively.

Case 1

A 30-year-old male presented with history of road traffic accident. The patient was a pedestrian who was hit by a truck. On arrival in ED, primary survey showed patent airway and normal breathing; patient was hemodynamically stable with Glasgow coma scale (GCS) E4V4M5 along with bilateral pupils of normal size and reactive to light. He was moving all four limbs, although there was pain and swelling of right thigh, and all peripheral pulses were normal.

Investigations

E-FAST examination was normal with normal chest and pelvic X-rays. X-ray of right thigh showed fracture of shaft of femur. Computed tomography (CT) head showed small contusion in right frontal lobe with large contusion in left frontal region along with associated edema. Pneumocephalus was seen in bilateral frontal region (►Fig. 1) with bilateral frontal fracture and right ethmoidal, maxillary and mandibular fracture.

Noncontrast CT (NCCT) face showed bilateral Le-Forte 1 and 2 fractures (►Fig. 2). Contrast-enhanced CT (CECT) chest and abdomen showed no evidence of intrathoracic injury, hemothorax/pneumothorax, no solid organ or hollow viscus injury, and no evidence of any intraperitoneal free air/liquid.

Treatment

Patient was managed nonoperatively with supine positioning, high-flow oxygen therapy, frequent neurological examination, and repeat imaging to look for increase in size of pneumocephalus and for significant pressure effect on the brain matter or ventricles. He underwent closed reduction and internal fixation for femur fracture. He improved neurologically during the course of his hospital stay and GCS improved to E4V5M6.

Outcome and Follow-up

He improved neurologically during the course of his hospital stay with conservative measures mentioned above and was discharged in stable condition. At the time of discharge, patient did not have any neurological deficits, was feeding orally, and voiding by self. At present, patient is doing well with no residual neurological deficit and did not require any further neurosurgical intervention for any complications.

Case 2

A 67-year-old male presented with history of road traffic accident. Patient was a pedestrian who was hit by a two-
wheeler. On arrival in ED, primary survey showed patent airway and normal breathing; patient was hemodynamically stable with GCS E3V4M5 with left pupil of normal size and reactive to light and right pupil nonassessable due to periorbital swelling. He was moving all four limbs, and all peripheral pulses were normal. Clinically, there was no facial bone/long bone fractures.

**Investigations**

FAST examination was normal; however, E-FAST showed left-sided PneumoScan positive with normal chest and pelvic X-rays. CT head showed pneumocephalus (Fig. 2) with multiple hemorrhages in gray–white junction, suggestive of diffuse axonal injury. In addition, there was left frontal bone fracture involving left frontal sinus with hemosinus. CECT torso showed mild left-sided hemopneumothorax with no evidence of any rib fractures, no solid organ or hollow viscus injury, and no evidence of any intraperitoneal free air/fluid.

**Treatment**

Patient was managed conservatively with supine positioning, high-flow oxygen therapy, frequent neurological examination, and repeat imaging to look for increase in size of pneumocephalus and for significant pressure effect on the brain matter or ventricles.

**Outcome and Follow-up**

The patient was managed conservatively and discharged after complete neurological recovery and with no major neurological deficits. Patient is doing well postdischarge with complete neurological recovery and has not required further neurosurgical intervention for any complications.

**Discussion**

First described by Lecat in 1741, pneumocephalus is described in various clinical settings. While pneumocephalus is quite often seen in the setting of trauma and postsurgery, especially posthead and neck or neurosurgical interventions, tension pneumocephalus is quite rare and a form of neurosurgical emergency. Tension pneumocephalus was first described by Ectors, Kessler and Stern in 1962. It occurs when air in the cranial cavity exerts pressure on the brain matter or ventricles. Prompt and accurate diagnosis of this condition is absolutely vital to prevent mortality or poor neurological outcomes. This requires a high index of clinical suspicion and corroborative imaging in the appropriate clinical setting.

The most common clinical presentations include headache, vomiting, lethargy, decreased vision, altered mental status, CSF rhinorrhea, and stupor. Definitive diagnosis in most cases require imaging, most commonly a plain CT scan showing characteristic Mount Fuji sign or showing dural air in any compartment with features of raised intracranial tension (ICT). This sign is characteristic of tension pneumocephalus and is characterized as bilateral frontal subdural air on CT with widened interhemispheric fissure due to compression and separation of frontal lobes by subdural air. It suggests that pressure of the gas is at least greater than the surface tension of CSF between the frontal lobes. It is caused by cortical veins tethering the frontal lobes, resulting in this characteristic appearance. In the emergency department, optic nerve sheath diameter can be used to look for signs of raised intracranial pressure (ICP).

Management includes supine positioning, 100% oxygen via nonrebreathing mask, serial optic nerve sheath diameter measurement, regular monitoring of neurological status, repeat imaging in case of deterioration of neurological status and, if required, simple twist drill and aspiration of intracranial air with or without an underwater seal, craniotomy, drilling of burr holes, ventriculostomy placement and closure of dural defects.

**Learning Points**

1. Tension pneumocephalus should be suspected in patients with craniofacial fractures, including those with blunt or penetrating trauma with decreased neurological status.
2. Early identification is important for optimal survival and neurological outcome. Such patients should be constantly monitored for worsening of neurological status and features of increased pressure on brain matter, so that early neurosurgical intervention can be done.
3. Definitive diagnosis depends on imaging.
4. Management includes both nonoperative measures like supine positioning, 100% oxygen, and frequent assessment of neurological status.
5. Early neurosurgical consultation and urgent decompression, if required, is necessary in cases showing significant pressure effect due to prevent neurological deterioration.

**Authors’ Contributions**

U.K. and A.A. were involved in patient management. U.K. and T.P.S. did the interpretation of clinical images. A.A. wrote the first draft of the manuscript, and T.P.S. and S.B. reviewed and edited the final version. All authors take full responsibility of the manuscript.
