Abstract

Background Carpal tunnel syndrome (CTS) is the most common entrapment neuropathy which can cause severe sleep disturbance. Carpal tunnel release (CTR) is a choice for severe cases, which has shown to improve sleep quality, but the available evidence is limited. This study aimed to investigate the impact of CTR on sleep quality and hand symptoms and functions in patients with CTS.

Methods This was a prospective study in 2019–2020 on patients with CTS and poor sleep quality undergoing CTR. Patients were evaluated before and at 1, 3, and 12 months after CTR by the Pittsburgh sleep quality index (PSQI) and Boston carpal tunnel syndrome questionnaires.

Results There were 33 patients with 27 females (82%) and a median age of 51 years. The median time of CTS diagnosis and having sleep disorder before CTR were 12 and 6 months, respectively. The outcomes significantly improved after CTR, with the median PSQI and Boston symptom and function scores reduced from 12, 33, and 23 before CTR to 9, 14, and 11 at 1 month; 7, 13, and 9 at 3 months; and 1, 11, and 8 at 12 months postoperatively, respectively. The correlations between the PSQI and Boston symptom and function scores were > 0.6 at all time-points.

Conclusions Surgical decompression significantly improves sleep quality and the hand symptoms and functions in patients with CTS. Long-term evaluations are lacking and thus are required in future studies.

Introduction

Carpal tunnel syndrome (CTS), first described by Sir James Paget in 1854,1 is the most common entrapment neuropathy of the upper extremity. This disease has been reported to affect mostly women.2 It is characterized by numbness, tingling, and pain in the median nerve distribution.3,4 Pain and numbness in nighttime has also been reported as common symptoms of CTS. Night waking with numbness

due to wrist position is an important problem of CTS which hinders the ability to sleep well.3,5,6 Disrupted sleep is also common in patients with CTS, with approximately 80% of patients with CTS having nighttime waking due to numbness.7 Due to frequent nighttime awakening and fragmented sleep, CTS also increases daytime sleepiness and dysfunction. Thus, relief of nighttime symptoms plays a key role in the treatment of CTS. While most conservative treatments do not work well with CTS with severe manifestations (e.g., nighttime symptoms), surgery is necessary. Carpal tunnel release (CTR) has shown to improve sleep disturbance in patients with CTS,8–13 however, the available evidence is limited, as the number of reported studies as well as their sample sizes are small. Therefore, we performed this study in order to investigate the impact of CTR on sleep quality and the symptoms and functions of the hand in patients with CTS and poor sleep quality.

Methods

Study Design and Population
This was a prospective study from May 2019 to September 2020 at a tertiary referral hospital in Ho Chi Minh city, Vietnam. The study was approved by an Independent Ethics Committee before recruiting any patient. We consecutively recruited patients older than 18 years of age with confirmed diagnosis of CTS who underwent CTR with existing preoperative diagnoses of poor sleep quality. Exclusion criteria were as follows: (1) comorbidities of other neurological diseases such as polyneuritis and brachial plexus disorders, and (2) lost to follow-up at all scheduled visit after the surgery. The diagnosis of CTS was in accordance with the clinical practice guideline approved by the American Academy of Orthopaedic Surgeons.14,15 Patients were diagnosed with poor sleep quality preoperatively when the global Pittsburgh sleep quality index (PSQI) score was more than five. The indications of surgery for patients with CTS included the denervation of the abductor pollicis brevis muscle, sensory loss, or pain unresponsive to conservative treatments. Written informed consent was obtained from all patients before enrollment.

Assessment and Follow-Up of Patients
Demographic, clinical data, PSQI, and the Boston carpal tunnel syndrome questionnaire were used to assess the function and severity of the disease preoperatively. All patients underwent median nerve decompression through a limited palmar incision by a single experienced surgeon. Wrist splint and pharmacotherapy were used during 2 weeks after surgery. Sleep quality and severity of symptoms were evaluated at 1, 3, and 12 months postoperatively by the PSQI and Boston carpal tunnel syndrome questionnaire.

The PSQI is a self-rated questionnaire that can assess sleep quality and disturbances over a 1-month period.16 It consists of 19 individual items which generate the following seven components: sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction. Each component is scored from zero to three, with zero representing no problem and three representing the worst sleep quality. The total score of these seven components yields the global PSQI score. The higher the score, the worse sleep quality that the patient complains of. Since all patients did not use pharmacological or medical support for sleeping problems, all were given a score of zero for the sixth component (use of sleeping medication) and this component was excluded from the analysis.

The Boston carpal tunnel syndrome questionnaire,17 also called the Levine–Katz Questionnaire, is also a self-administered questionnaire which assesses the severity of symptoms and functional status in patients with CTS. It has 19 questions: 11 dealing with symptom and eight with function. Each question is scored from one (the mildest) to five (the most severe). A higher score indicates more severity of the patient’s symptom and function.

Statistical Analysis
Patients’ characteristics and study outcomes (PSQI and Boston scores) were summarized by counts and percentages for categorical variables, and median and interquartile range (IQR) for continuous variables. The longitudinal measurements of the outcomes were presented graphically for males and females. We compared the differences of the scores between each time-point before and after CTR using Wilcoxon signed rank test. Correlation between PSQI and Boston symptom score and Boston function score were analyzed by Spearman’s correlation coefficients. All tests were two-sided and statistical significance was defined when p-value was <0.05. All analyses were performed using the statistical software R version 3.6.3 (R Foundation for Statistical Computing, Vienna, Austria).

Results
A total of 33 patients were included in the study with females predominating (27 cases, 82%) and median age of 51 years (range: 33–71). Median duration of confirmed CTS before undergoing the surgery was 12 months (range: 5–36), whereas median duration of having sleep disorder was 6 months (range: 2–12). There was no patient with hypothyroidism or rheumatoid arthritis. All patients had received conservative treatment with the median preoperative duration being 8 months (range: 3–18). Eight patients (24%) underwent CTR in both hands (►Table 1).

Median global PSQI score was 12 (range: 8–16) before surgery and decreased to 9 (range: 6–15) at 1 month, 7 (range: 5–10) at 3 months, and 1 (range: 0–9) at 12 months postoperatively, with significant differences (►Table 2, ►Fig. 1). The analysis of each PSQI component also showed significant improvement in all components after surgery (►Table 2). With regard to the Boston symptom and function scores, the results were similar, with a significant improvement in the hand symptom and function scores from before to after surgery.
The improvement of these scores were similar in males and females (Fig. 1).

The PSQI global scores had a significant and highly positive correlation with the Boston symptom and function scores. The correlation was consistent from before to after surgery, with the Spearman’s correlation coefficients being $>0.60$ in all analyses (Fig. 2).

**Discussion**

This study shows consistent improvements of sleep quality as well as the symptoms and functions of the hand at 1 to 12 months after CTR, according to the PSQI and Boston symptom and function scores. The study also demonstrates that sleep quality highly correlates with the hand symptom and function scores. As good sleep quality is important and can reduce the risk of stress, depression, hypertension, overweight and obesity, it is important for patients to undergo CTR when having indication.

Abbreviations: IQR, interquartile range; PSQI, Pittsburgh sleep quality index.

Note: Summary statistics are median (IQR), $p^{0,1}$ is for testing change from before surgery to 1 month, $p^{1,2}$ is for testing change from 1 to 3 months. $p^{2,3}$ is for testing change from 3 to 12 months. All $p$-values are based on Wilcoxon signed rank test.
Sleep symptoms are frequent in patients with CTS and cause a huge impact on their quality of life, but they have just got more attention since several years ago. The seriousness of sleep disorder is thought to associate with the grade of nerve entrapment. This is somehow proved in our study by the strong positive correlation between the PSQI score and Boston symptom and function scores: the more severe symptom is associated with the worse sleep quality. Although both questionnaires are subjective, the consistent results of these correlations at multiple time-points before and after surgery would minimize the potential subjective bias. In addition, other studies also reported the significant correlation between CTS symptom and functional severity with sleep quality, which consolidate the evidence of the association between CTS symptoms and sleep disturbance. Therefore, handling the symptoms is essential in order to solve the sleep problem of patients with CTS. In patients with long time of having CTS, especially those with poor sleep quality due to CTS, most conservative treatments do not work well and surgery is the only choice. Indeed, CTR has shown its effectiveness in CTS by the significant improvement in the hand’s symptoms and functions as well as sleep quality. In our study, the early improvements are more marked for the symptoms and functions of the hand, whereas the sleep quality improved more slowly. However, our study and others have a relatively short follow-up period (less than 1 year), so long-term outcomes of patients are still lacking, as in our results, some patients tend to be worse from 3 to 12 months after the surgery, with respect to both the PSQI and Boston symptom and function scores.

Limitations of the study included lack of a control group without surgery and potential selection bias due to a single-centre design with single surgeon’s practice. A comparable multicenter study would confirm and generalize the results better. However, a control group with similar disease severity is hard to get because surgery is indicated for patients with pain unresponsive to conservative treatment. Second, recall bias, which is inherent in all questionnaires, maybe present in this study. However, the consistent improvement of the scores via assessing all patients several times before and after surgery could minimize this potential bias. Third, sleep quality was not evaluated using polysomnography. Therefore, obstructive sleep apnea, which was reported to have higher frequency of CTS, could not be excluded in this study.

In conclusion, surgical decompression significantly improves sleep quality and the symptom and function of the hand in patients with CTS and poor sleep quality. These improvements start right after the surgery and remain until 12 months. The study also confirms that the PSQI and Boston symptom and function questionnaires are applicable instruments to quantify the results after CTR. More studies with long-term follow-up are needed, as there is lack of long-term results of the surgery in the treatment of CTS.
