Analysis of Serum Cholesterol, Statins and Atherosclerotic Plaque in Ruptured and Unruptured Intracranial Aneurysm

Abstract

Introduction Intracranial aneurysm (IA) is a major healthcare concern. The use of statin to reduce serum cholesterol has shown evidence to reduce cardiovascular risk in various diseases, but the impact on IA has not been described. This study aims to determine whether statin use, and serum cholesterol levels interfere with outcomes after IA event.

Methods A cohort of patients with IA was analyzed. Patients social and demographics data were collected. Modified Rankin scale (mRS) score after 6 months of follow-up was the endpoint. The data regarding statins use, presence or not of atherosclerotic plaque in radiological images and serum cholesterol of 35 patients were included in our study. Linear regression models were used to determine the influence of those 6 variables in the clinical outcome.

Results The prevalence of atherosclerotic plaque, high cholesterol and use of statins was 34.3%, 48.5%, and 14.2%, respectively. Statins and serum cholesterol did not impact the overall outcome, measured by mRS after 6 months ($p > 0.05$), but did show different tendencies when separated by IA rupture status. Serum cholesterol shows an important association with rupture of aneurysm ($p = 0.0382$). High cholesterol and use of statins show a tendency for worse outcome with ruptured aneurysm, and the opposite is true for unruptured aneurysm. The presence of atherosclerotic plaques was not related with worse outcomes.

Keywords ► cholesterol ► statins ► plaques ► outcomes for IA
Conclusions  Multiple and opposite mechanisms might be involved in the pathophysiology of IA. Ruptured aneurysms are associated with higher levels of serum cholesterol. Serum cholesterol and statins use were not correlated with worse outcomes, but further studies are important to clarify these relationships.

Introduction  Intracranial aneurysm (IA) is a major healthcare concern. It is defined as a dilation of a cerebral blood vessel. Aneurysms are considered as the consequence of an abnormal blood flow. Increased hemodynamic stress leads to vessel damage and subsequent inflammation. The inflammatory process can be harmful to the vessel, leading to apoptosis of its smooth muscle cells and to progressive weakening of the vessel, as they are the primary matrix-synthesizing cells in the vessel.  

The lesions are widely spread in the adult population. Some studies suggest that the prevalence of IA among this group can reach up to 5%. Clinical prognosis can vary widely depending on the size of the lesion. Subarachnoid hemorrhage (SAH) is a major complication, occurring in about 6 to 7 persons annually, 85% of which can be directly attributed to aneurysm rupture. Almost 2/3 of patients end up with a poor outcome such as death, or permanent disabilities. The case fatality after SAH can reach up to 50% and even though it is more likely to happen in older people, half of the patients are under 55 years.  

Many attempts have been made to predict patient outcome after SAH with mixed results. Most studies use a combination of methods, including versions of the modified Rankin scale (mRS) and Glasgow outcome scale (GOS), as well as variables such as the patient’s gender, age, history and aneurysm size and location. The lack of consistency and precision in the methods used casts doubt on their ability to predict outcomes reliably. A prime concern among patients with IA is arterial embolism; thromboembolisms occur when atherosclerotic plaques have their lipidic core exposed to the bloodstream. Large thrombotic occlusions can happen either in the anterior or posterior intracranial circulation, resulting in cortical symptoms, as well as medullary and pontine infarction syndromes, respectively. Atherosclerotic lesions are relatively common in patients with IA, with one study finding some visible atherosclerotic alterations in 37% of the patients during operations.  

The formation and progression of atherosclerotic plaques is a multifactorial process, but one key contributor to it is the low-density lipoprotein cholesterol (LDL). When deposited in the vessel’s wall, LDL oxidizes, attracting monocyte-derived ...
cells to the lesion’s site. Those cells penetrate the vessel wall due to its reduced integrity, reaching the sub endothelial space where they will differentiate into mature macrophages. Those macrophages will eventually internalize the lipoproteins to form the foam cells and the plaque.\textsuperscript{12,13} Therefore, it stands to reason that the inhibition of LDL synthesis could prove to be an effective way of preventing strokes. Some of the major drugs capable of affecting LDL synthesis are statins, competitive inhibitors of HMG-CoA reductase that end up inhibiting overall lipoprotein synthesis in the liver and, consequentially, LDL production.\textsuperscript{14} Additionally, it has been found that statin increases the high-density lipoproteins (HDL),\textsuperscript{15} which have been linked with atherosclerotic plaque regression.\textsuperscript{16}

Cholesterol levels have also shown association with other vascular diseases,\textsuperscript{17} and while lower levels of LDL and higher levels of HDL are associated with the prevention of atherosclerotic plaque formation, the opposite is true regarding the prevention of SAH,\textsuperscript{18} making the role of statin in IA even more unclear.

As there is evidence to support the efficacy of statin in the prevention of strokes,\textsuperscript{19} this study aims to investigate the possible correlation between statins, serum cholesterol levels and outcome for IAs after 6 months.

**Methods**

**Study Design**

This is a prospective single-center cohort study with patients who were admitted in the hospital due to SAH, between January 2018 and November 2019. All patients were treated with either microsurgery or embolization. Social and demographic data were acquired from charts of patients from the department of neurosurgery of the Hospital das Clínicas (HCFMUSP) database. It was also collected information about statins use, high cholesterol levels, presence of atherosclerotic plaques with radiological image, and aneurysm intracranial rupture status upon admission. The mRS scores were collected prospectively at 6 months of follow-up.

**Population Data**

The study recruited 401 patients (adult men and women) from the Department of Neurological Surgery of the Hospital das Clínicas da FMUSP (HCFMUSP). After admission, the patients were divided in two groups: the first included patients with SAH and ruptured aneurysm (244), and the second included patients with unruptured aneurysms undergoing elective surgery (177).

Data from 401 patients were analyzed, and 35 were included in this study (~Fig. 1). All 35 patients with data for serum cholesterol, use of statins, and presence or not of atherosclerotic plaque were followed for 6 months for outcome evaluation.

A questionnaire concerning previous risk factors to aneurysmatic disease was performed, which included hypertension, smoking, alcoholism, drug abuse, family history, previous SAH and date of the last event. Besides that, a socioeconomic evaluation of the participants was performed, assessing: educational level, family income, occupation, and marital status. Patients were followed for 6 months. At the end of the study, mRS and GOS were used to measure outcome after SAH.

**Exclusion Criteria**

Patients with missing cholesterol and statins use data, radiological images for atherosclerotic plaques status, or who stopped attending the follow-up appointments in less than 6 months were excluded from the study.
Inclusion Criteria
All patients were included, regardless of gender and age, with ruptured and unruptured brain aneurysms who were admitted to HCFMUSP between January 2018 and November 2019. Patients with high-grade SAH, rated 4 or 5 in the Hunt Hess scale, were not included.

Statistical Analysis
We used univariate linear and logistic regressions with statin use, presence of atherosclerotic plaques, and high cholesterol as independent and dichotomous variables. High cholesterol was defined as a serum cholesterol higher than 200 mg/dl. Serum cholesterol at admission was also used as an independent and continuous variable. The outcome was mRS at 6-months. Significance level was established as 0.05. For the logistic regression, unfavorable outcome was defined as mRS score greater than 2.

Patients were also divided in ruptured and unruptured aneurysm groups. The prevalence of statin use between the groups was analyzed with Fisher exact test for categorical data. A significance level of 0.05 was used.

Results
Epidemiology and Comorbidities
Among the 35 patients included in the study, the average age was 57.71 ± 9.79 years, and 91.4% were male. Hypertension was present in 62.9% of the patients, 22.9% had previous diabetes mellitus, 37.1% were smokers, 14.3% were heavy alcohol drinkers and 42.9% patients had ruptured aneurysm. (►Table 1). Regarding treatment, 6% were treated with embolization and 93% with microsurgery. No patients had previous history of ruptured aneurysms.

Abbreviations: GOS, Glasgow outcome scale; GCS, Glasgow coma scale; mRS, modified Rankin scale; SAH, subarachnoid hemorrhage. Data is presented as mean (SD) for continuous variables, and count (%) for categorical variables. Patients were divided in ruptured and unruptured aneurysm. P-value shows comparison between groups.

Serum Cholesterol and Outcome
The median Glasgow coma scale (GCS) at admission in the hospital was 14.

The mean value of serum cholesterol in the group with unruptured aneurysm was 195.2, and in the ruptured aneurysm group was 211.6. This difference was not statistically significant (p > 0.05). The mRS score at 6 months was on average 1.4 ± 0.91. The mean serum cholesterol upon admission was 202.25 ± 46.28 (►Fig. 2). A total of 17 patients had cholesterol levels higher than 200 mg/dl, with 52.9% being in the ruptured aneurysm group.

The linear regression using cholesterol as a predictor and the mRS score at 6 months shows that cholesterol does not have a statistically significant influence in the outcome measured by the mRS (p > 0.05). However, adding an interaction term for serum cholesterol and rupture of aneurysm, the linear regression model shows that these two variables are influenced by one another (p = 0.0382).

Despite the fact serum cholesterol itself does not show a significant influence, high cholesterol shows a tendency for...
worse outcomes in the ruptured aneurysm group (0.76 increase in mRS score for every 100 mg/dl increase in serum cholesterol [-0.05; 1.57], \( p = 0.064 \)), but a tendency for better outcomes in the unruptured aneurysm group (-0.705 mRS score decrease for every 100 mg/dl increase in serum cholesterol [-1.87; 0.46], \( p = 0.223 \)).

**Statin and Outcome**

In the unruptured aneurysm group, 20% were using statins. In the ruptured aneurysm group, only 6.7% were using this medication. This difference was not statistically significant (\( p > 0.05 \)) (~Fig. 3).

The linear regression with "use of statins" as a predictor and the mRS scale score at 6-months shows that statins do not have a statistically significant influence in the outcome measured by the mRS (\( p > 0.05 \)).

The sub analyses with ruptured and unruptured aneurysm show no difference in either group (\( p > 0.05 \)). However, while patients using statins had a tendency for worse outcomes in unruptured aneurysm (0.125 increase in the mRS at 6 months [-1.07; 1.32]), statin use was correlated with better outcomes in ruptured aneurysm (-0.429 decrease in the mRS at 6 months [-2.33; 1.47]) (~Table 2).

**Atherosclerotic Plaques and Outcome**

In the unruptured aneurysm group, 35.0% had atherosclerotic plaques. In the ruptured aneurysm group, only 33.3% presented atherosclerotic plaques. This difference was not statistically significant (\( p > 0.05 \)).

All atherosclerotic plaques were directly correlated with the aneurysm's site, with 11 cases (32.3%) being in the posterior communicating artery, 10 (29.4%) in the middle cerebral artery, 6 (17.6%) in the anterior communicating artery, 5 (14.7%) in the internal carotid artery and 2 (5.8%) cases in the anterior cerebral artery.

Serum cholesterol, use of statins, and presence of atherosclerotic plaque were used as independent variables. Multiple linear regression scale measured at 6 months was defined as outcome.
The linear regression with “presence of atherosclerotic plaque” as a predictor and the mRS score at 6-months shows that atherosclerotic plaques do not have a statistically significant influence in the outcome measured by the mRS ($p > 0.05$).

The sub analyses with ruptured and unruptured aneurysm show no differences in either group ($p > 0.05$). There was also no statistically significant difference in the distribution of ruptured and unruptured aneurysm based on the mRS at 6 months ($p > 0.05$) (Fig. 4).

**Discussion**

There are many ways already used to predict IA outcome. The World Federation of Neurological Surgeons' (WFNS) Grading System for Subarachnoid Hemorrhage scale correlates lack of ruptured aneurysm and higher levels of consciousness with better outcomes. Further research seems to indicate that advanced age and larger aneurysms contribute to worse outcomes. Notably, cholesterol levels and the presence of atherosclerotic plaques are absent from these scales, despite being so intertwined with the disease’s pathophysiology that it would not be unreasonable to think they may have some impact in its outcome.

The serum cholesterol level may be absent from most outcome predictors, but we can find it somewhat indirectly in statin research. The role of statins as a preventive factor in IA remains ambiguous in the literature. In some animal models it has been found that they could either halt or promote IA progression. In clinical studies however, no correlation was found between statin use and IA prevention, aligning with our findings.

Even though the biochemical role of statins in reducing the inflammatory processes in the vessels walls is largely understood, it doesn’t seem to correlate with actual clinical studies when it comes to IA prevention. The inflammatory process in the vessel where macrophages turn into foam cells and form plaques can be attributed to LDL, as its oxidized form is incorporated into these cells. The oxidized LDL induces the vessel’s endothelium to express certain molecules that allow monocytes to adhere and infiltrate the vessel. Because statins reduce LDL and oxidized LDL levels, the logical conclusion would be that they should be beneficial to prevent intracranial aneurysms. Since this assertion is not verified by clinical trials, inflammation does not fully explain the underlying causes of IAs, and other factors are probably at play.

Despite the lack of statistical significance in our study regarding the tendency of higher levels of cholesterol to correlate with worse outcomes, other studies could verify this relation. Measuring cholesterol as a whole might be problematic when it comes to outcome. Systematic reviews and meta analyses show that even though hemorrhagic strokes are negatively correlated with total cholesterol levels, only a higher level of HDL is positively associated with hemorrhagic strokes, LDL being the opposite.

One possible reason for this phenomenon would be that low levels of cholesterol could promote necrosis in the arterial medial layer’s smooth muscle cells making the vessel more likely to suffer microaneurysms. Another theory claims that low cholesterol may reduce platelet aggregability, thus making hemorrhage more likely. This might explain why we couldn’t find a correlation between statin use and better outcomes, as it primarily reduces LDL levels and the increased likelihood for hemorrhagic stroke may mitigate their benefits. It is important to note that statin therapy was not associated with increased risks of hemorrhage.

It has already been established that atherosclerosis is the underlying pathological basis of strokes, coronary artery disease, peripheral artery disease, and hypertension. However, being the cause of the disease does not necessarily mean that the maintenance of cholesterol levels are the main contributors to negative outcomes. As a matter of fact, high cholesterol is only the sixth risk factor regarding attributable deaths in heart attacks and strokes. Furthermore, literature is scarce when it comes to IA specifically, making it hard to determine if the maintenance of cholesterol levels is as important in intracranial aneurysms as it is in other cardiovascular diseases. Despite the fact that our results could not establish any significant change regarding presence or not of atherosclerotic plaques and clinical outcomes, more research is required in the subject.

The relatively small number of patients with concomitant data for statin use, serum cholesterol level and presence of atherosclerotic plaque, might explain the lack of statistical significance for some variables in our study. Moreover, a clinical trial with randomization of treatment with statins and a longitudinal control of serum cholesterol levels is also necessary for a definitive answer. Other limitations include the lack of a model with more variables that affect presence or not of atherosclerotic plaques and clinical outcomes, more research is required in the subject.
cholesterol levels and outcome, the investigation of other pathophysiological components of IA may prove helpful in determining a more accurate outcome.

**Conclusion**

Intracranial aneurysm is an important healthcare problem, and understanding the factors that might have an influence in the outcome of IA is key for an adequate treatment. Our results show that there is no statistical significance to prove that use of statins, serum cholesterol and the presence of atherosclerotic plaque correlate with worse outcomes, even though ruptured aneurysms were associated with higher levels of serum cholesterol. Multiple and opposite mechanisms might be involved in the circumstances of IA and further studies are needed to describe and understand the pathophysiology specific for IA.
