Late transmural mesh migration into the esophagus after Nissen fundoplication

A 71-year-old woman was referred to the gastroenterology department with progressive dysphagia and weight loss over 4 weeks. She had undergone a laparoscopic fundoplication with closure of the hiatal crura with mesh 5 years previously for heartburn due to gastroesophageal reflux disease and a large hiatal hernia.

Upper gastrointestinal endoscopy showed an irregularly shaped foreign body obstructing the lumen immediately proximal to the cardia (● Fig. 1 a). This was assumed to be a food bolus, so the object was extracted using a Roth net standard retriever. Surprisingly, the foreign body proved to be a surgical mesh (● Fig. 1 b).

The esophageal wall was again inspected after this endoscopic extraction. There was evidence of severe lumen tortuosity and ulcerated stenosis at the gastroesophageal junction, and the opening of a fistula was found 1 cm above the cardia on the anterior wall of the esophagus (● Fig. 2). Thoracoabdominal computed tomography (CT) scanning confirmed an intrabdominal air collection at the level of the fundoplication and a line of air to the esophagogastric fistula (● Fig. 3 a). A covered self-expanding metal stent (Hanarostent; 80×14mm) was inserted to treat both the esophageal stricture and the fistula (● Fig. 3 b). There were no complications during the procedure, following which the patient reported no dysphagia (grade 0).

The stent was removed 6 weeks later without complications and complete healing of the fistula was confirmed. A further CT scan showed reduction of the intra-abdominal air collection (● Fig. 3 c) with the patient reporting weight gain and no symptoms of dysphagia.

Closure of the hiatal crura has proven to be a fundamental issue in laparoscopic antireflux surgery [1]. Mesh reinforcement is not without complications and the incidence of these complications may be greater than previously reported [2, 3].

We describe a rare case of dysphagia caused by an esophagogastric fistula that was secondary to complete transmural esophageal migration of the surgical mesh 5 years after Nissen fundoplication and was resolved by endoscopic management.
