Introduction

Intracranial arachnoid cyst is the most common cystic congenital anomaly in the brain.1–5 The prevalence and natural history of arachnoid cyst in children are ambiguous.1,3–5 With the increased use of magnetic resonance imaging (MRI) and computed tomography (CT) imaging, there has been a corresponding rise in the number of incidental discoveries of arachnoid cysts.6 Studies have proposed that the pediatrics population has a prevalence rate of 2.6%.6 In addition, a male predominance with a male to female ratio: 2:1 is noted in the pediatrics community.2,6,7 We describe a case of a large symptomatic posterior fossa arachnoid cyst with hydrocephalus manifesting at the age of 18 months. Incidentally, the series of antenatal ultrasound scans were normal. We intend to discuss the pathogenesis of arachnoid cyst.

Case Report

A healthy 33-year-old woman was into her first pregnancy. She was diagnosed with gestational diabetes in the third trimester managed throughout with dietary and lifestyle adjustments. Antenatally, the fetus was monitored with serial ultrasound scans that showed normal growth velocity. The serial ultrasound scans between 10 and 38 weeks of gestation demonstrated biparietal diameter corresponding to gestational age (►Table 1). She had a fetal anomaly scan at 24 weeks, 5 days that was reported normal. The central nervous system structures were visualized noted to be normal (►Fig. 1). The other systemic organs and the cerebellum and ventricles were reported to be normal (►Fig. 2).

A healthy baby boy was born via spontaneous vaginal delivery at 38 weeks of gestation with an APGAR

Abstract

Intracranial arachnoid cyst is the most common cystic congenital anomaly in the brain. In this study, we discuss a pregnancy that had serial fetal ultrasound scans throughout the pregnancy and a fetal anomaly scan at 24 weeks of gestation that was normal. The child was born healthy with normal development, but 12 months onward the head began to enlarge. The magnetic resonance imaging of the brain showed a large posterior fossa arachnoid cyst with hydrocephalus. We discuss the postulation to explain this pathogenesis of the cyst. This case highlights that not all symptomatic arachnoid cysts are congenital despite the manifestation being as early as infancy.

(appearance, pulse, grimace, activity, and respiration) score of 10 at 1 and 5 minutes. The delivery was uneventful. The birth weight was 3.15 kg. The head circumference was 33 cm that was within the normal range (► Supplementary Fig. S1; available in the online version only). He was a healthy child and developing as per the chronological milestones. From the age of 12 months onward, he was detected to have a rapid rise in head circumference over the subsequent 6 months (► Supplementary Fig. S1). He had some delay in the gross motor milestone; at the age of 18 months, he could not walk independently. The eye movements were normal. There was some speech delay as at the age of 18 months, he could only manage to say some monosyllabic words example “mama” and “bye” and still uses nonverbal gestures. The hearing assessment was normal. There is no history of meningitis or any form of head injury.

An MRI brain was performed at 18 months of age. It showed a large retrocerebellar cyst with the dimension of $7.6 \times 7.3 \times 10.5$ cm which was causing significant hydrocephalus. The vermis of the cerebellum was present (► Fig. 3). The radiological diagnosis was befitting a large retrocereellar arachnoid cyst. The possible differential diagnosis to be considered includes Blake’s pouch cyst, Dandy-Walker variant, and epidermoid cyst. Mega cisterna magna typically does not cause hydrocephalus.

Given the symptomatic nature of the arachnoid cyst, the child had stereotactic endoscopic fenestration of the cyst into the right lateral ventricle via a frontal burr hole and a third ventriculostomy. The content of the cyst at fenestration was the cerebrospinal fluid. The surgery was uneventful. Three months after the surgery, the child had started to walk independently, and his speech improved with the utilization

of at least 10 words in the vocabulary. The MRI brain 3 months later showed a smaller arachnoid cyst and ventricles (Fig. 4).

Discussion

Arachnoid cysts are mostly described as congenital lesions. Most cases are asymptomatic and are detected while performing a workup for other cranial indications, for example, headaches, developmental delay, or raised head circumference.1,8 There are cases detected incidentally during workup for seizure or trauma. Arachnoid cyst can be acquired secondary to head trauma, brain infection, or postcranial surgery. Retrospective studies of arachnoid cyst prevalence do not differentiate between congenital and acquired arachnoid cysts, but acquired cysts are believed to be a minority of cases.1,8,9 In a few studies in English literature, there were reported subjects with prior normal CT brain imaging presenting later with a de novo suprasellar arachnoid cyst.7,10

The long-term behavior of the cyst is variable as there are reported cases of arachnoid cysts that become larger or smaller, and, in some cases, it resolves spontaneously.1,11,12 Symptomatic arachnoid cysts can be surgically treated with endoscopic fenestration, craniotomy for fenestration, or shunt placement, but these surgeries are associated with potential morbidities.12–18 In a study on 111 patients with asymptomatic intracranial arachnoid cyst who had undergone MRI follow-up for more than 5 months without treatment, approximately 10% (11 cases) increased in size, 12% (13 cases) decreased in size, and 78% (87 cases) remained stable after 3.5 years.1 The mean age group of the cohort is 6.4 years.1 Symptom attributed to the enlargement of cyst only developed in three patients, and they opted for surgical treatment.1 In another retrospective study, out of 309 patients with asymptomatic intracranial arachnoid cyst who underwent follow-up, only 6.8% (21 cases) patients developed symptoms and underwent surgical treatment.1 The natural history of the arachnoid cyst is mostly quiescent and asymptomatic.

This case adds to the body of literature that not all arachnoid cysts detected at infancy should be categorized as congenital lesions. The series of ultrasounds from 10 to 38 weeks of gestation did not detect an abnormal change in the cranial biometric measurements. The fetal anomaly ultrasound scan at 24 weeks of gestation did not detect any hydrocephalus or cerebellar cyst. The child began to...
manifest symptoms at 12 months of age, and this was monitored. However, the diagnosis of the arachnoid cyst was clinched at the age of 18 months. Therefore, this case highlights that detection of an arachnoid cyst at infancy is not synonymous with a congenital lesion. The case illustrates that the arachnoid cyst or the secondary effects of the arachnoid cyst, e.g., hydrocephalus, were not present antenatally. Therefore, two postulations can be entertained. The first postulation is a de novo formation of the arachnoid cyst after birth indicating an acquired phenomenon. The second postulation would be there could have been a small cyst that was present antenatally, but it was not visible as an anomaly during the fetal anomaly scan. This could mean the progression of the cyst to become symptomatic is a developmental process rather than a congenital manifestation. This case highlights that not all symptomatic arachnoid cyst is congenital despite the manifestation being as early as infancy.

In the context of many Asian countries, the insurance policies would not cover diseases and malformation that are deemed to have occurred during gestation (congenital). As a result, it is important to make the distinction if a cystic brain lesion is acquired or a congenital lesion. This case report shows a large cyst with secondary changes during childhood is not synonymous with a congenital lesion. A de novo formation of the cyst or developmental progression of the cyst is a possibility. By virtue of that, some of these patients should be able to make an insurance claim for surgical treatment. Therefore, the fetal anomaly scan detailing the central nervous system would potentially be an important investigation to prove whether a postnatal lesion is a congenital or acquired lesion.

**Conclusion**

This case report adds to the body of evidence on the pathogenesis of arachnoid cyst. It highlights that not all arachnoid cysts detected in childhood are congenital. The cyst could be a de novo formation after birth or a developmental process with the progression of a small arachnoid cyst to become symptomatic.
