Endoscopic dissection of a symptomatic giant gastric leiomyoma arising from the muscularis propria

Gastrointestinal (GI) subepithelial masses represent a heterogeneous group of lesions, ranging from benign to malignant, for which management is sometimes challenging [1, 2]. We report the case of an 85-year-old woman, with a history of coronary artery disease and chronic atrial fibrillation being treated with anticoagulant therapy, who underwent urgent upper GI endoscopy for hemorrhagic shock and melena. During this procedure, a giant, 15-cm, non-pedunculated mass that was ulcerated on top was found at the greater curvature of the anterior wall of the stomach (▶ Fig. 1).

The patient then underwent radial endoscopic ultrasonography (EUS; GF-UE160-AL5; Olympus), which showed a hypoechoic homogeneous intramural mass that was arising from the muscularis propria and was suspected to be a leiomyoma (▶ Fig. 2). In order to achieve a definitive diagnosis, EUS with fine needle aspiration (FNA) was performed (GF-UCT180; Olympus) using a 22-gauge needle (Expect-SlimLine; Boston Scientific). Histology and immunohistochemical staining revealed that the specimen was compatible with a leiomyoma (SMA positive, CD117 and CD34 negative). Total body computed tomography (CT) excluded metastatic disease.

Because this was a symptomatic hemorrhagic lesion and there was a need to continue anticoagulant therapy, an endoscopic dissection was performed. We used the HybridKnife T-type (ERBE Elektromedizin GmbH) and a solution composed of 250 mL normal saline, 2 mL indigo carmine, and 1 mL epinephrine. The procedure took 115 minutes and resulted in an en bloc specimen, with no complications occurring (▶ Fig. 3; ▶ Video 1).

Low molecular weight heparin was re-introduced 24 hours after the procedure and the patient was discharged 2 days later. Upper GI endoscopy and EUS performed 3 months later revealed a regular scar, without any remnant pathological tissue.

This case illustrates the feasibility and safety of endoscopic dissection of a symptomatic giant gastric leiomyoma, even in a high risk patient who was receiving ongoing anticoagulant therapy, in whom surgery would have carried considerable risk. Moreover, EUS-FNA achieved an accurate evaluation of the lesion’s layer of origin and its histopathologic characteristics, thereby allowing a definitive diagnosis to be made and the appropriate therapeutic option to be chosen.
