ABSTRACT
Introduction/Aim Considering the high prevalence of non-alcoholic fatty liver disease (NAFLD) in individuals with type 2 diabetes mellitus (DM2), we aimed to investigate the potential benefit of determining markers of oxidative stress, inflammation and dyslipidemia for prediction of NAFLD, as estimated with fatty liver index (FLI) in individuals with DM2.

Methods A total of 139 individuals with DM2 (of them 49.9 % females) were enrolled in cross-sectional study. Anthropometric and biochemical parameters, as well as blood pressure were obtained. A FLI was calculated.

Results Multivariate logistic regression analysis showed that high density lipoprotein cholesterol (HDL-c) and malondialdehyde (MDA) were independent predictors of higher FLI [Odds ratio (OR) = 0.056, p = 0.029; and OR = 1.105, p = 0.016, respectively]. In Receiver Operating Characteristic curve analysis, the addition of fatty liver risk factors (e.g., age, gender, body height, smoking status, diabetes duration and drugs metabolized in liver) to each analysed biochemical parameter [HDL-c, non-HDL-c, high sensitivity C-reactive protein (hsCRP), MDA and advanced oxidant protein products (AOPP)] in Model 1, increased the ability to discriminate patients with and without fatty liver [Area under the curve (AUC) = 0.832, AUC = 0.808, AUC = 0.798, AUC = 0.824 and AUC = 0.743, respectively]. Model 2 (which included all five examined predictors, e.g., HDL-c, non-HDL-c, hsCRP, MDA, AOPP, and fatty liver risk factors) improved discriminative abilities for fatty liver status (AUC = 0.909). Even more, Model 2 had the highest sensitivity and specificity (89.3 % and 87.5 %, respectively) together than each predictor in Model 1.

Conclusion Multimarker approach, including biomarkers of oxidative stress, dyslipidemia and inflammation, could be of benefit in identifying patients with diabetes being at high risk of fatty liver disease.
In addition, diabetic individuals with NAFLD have 2-fold increase risk for development and progression of cardiovascular disease [7], and also 2 to 3-fold higher risk of dying of chronic liver disease [8], compared to diabetic individuals without NAFLD.

The pathophysiological mechanism underlying NAFLD is not well elucidated. However, it is speculated that oxidative stress and inflammation are the key determinants of this hepatic manifestation of metabolic syndrome [9–11]. Namely, increased visceral adipose tissue is significant source of reactive oxygen species (ROS), higher pro-inflammatory adipokines and cytokines [12, 13], along with decreased antioxidant enzymatic [14] and non-enzymatic defense [15, 16], which altogether make the milieu of increased inflammation and oxidative stress [15, 17]. Furthermore, ROS impact insulin signalling pathways, thus leading to consequent insulin resistant state, increased free fatty acids hepatic influx, increased lipogenesis, as well as triglyceride storage, inducing hepatocytes dysfunction or death [18].

To our knowledge, there are no data examining the oxidative stress markers in relation to NAFLD in exclusively patients with DM2. Furthermore, considering the high prevalence of NAFLD in individuals with DM2, and its association with diabetes complications, we aimed to investigate the potential benefit of determining markers of lipids oxidative damage [e.g., malondialdehyde (MDA)], proteins oxidative damage [e.g., advanced oxidation protein products (AOPP)], as well as antioxidant enzyme [e.g., catalase (CAT)], inflammation and dyslipidemia for improvement the prediction of NAFLD, as estimated with fatty liver index (FLI) in a cohort of individuals with DM2.

Subjects and Methods

Study population

This cross-sectional study derived from a previous work aiming to evaluate the utility of visceral adiposity indexes in individuals with DM2 [19].

The study enrolled a total of 139 sedentary DM2 (of them 49.9 % females) who volunteered to participate in the study. All examined patients were recruited by the endocrinologist in the Center of Laboratory Diagnostics of the Primary Health Care Center in Podgorica, Montenegro, for their regular biochemical analyses check-up or laboratory Diagnostics of the Primary Health Care Center in Podgorica, Montenegro, for their regular biochemical analyses check-up.

Out of the total number of 362 patients with diabetes (207 men and 155 women), who were screened for the study, 139 of them met the criteria for inclusion in the study (71 men and 68 women).

The methods and assays used to include participants and to exclude disorders in participants with diabetes have been described in detail elsewhere [19].

Inclusion criteria for participation in the study were: sedentary patients (< 90 min of weekly exercise) with DM2. Diabetes cases were defined as self-reported diabetes, or with at least two elevated plasma glucose levels (fasting glucose ≥ 7.0 mmol/L, a random plasma glucose level of ≥ 11.1 mmol/L, or a plasma glucose level ≥ 11.1 mmol/L 2 h after an oral glucose tolerance test), or HBA1c ≥ 6.5 % on two different occasions in the absence of symptoms; or treatment with antidiabetic medication (insulin or oral antihyperglycemic agents) [19].

Exclusion criteria were: type 1 diabetes mellitus, liver disease other than NAFLD, ethanol consumption > 20 g/day, acute inflammatory disease, high sensitivity C-reactive protein levels (hsCRP) > 10 mg/L, pregnancy, history or the presence of malignancy, as well as participants who were unwilling to enter the study [19].

Non-alcoholic fatty liver disease is assessed by FLI, as described previously [2, 20]. A FLI score ≥ 60 has been shown to have good specificity (80.3 %) and sensitivity (87.3 %) for established NAFLD, as reported previously [5, 21].

Although a FLI < 30 is regarded to exclude fatty liver, and that FLI ≥ 60 is suggestive of fatty liver, we have excluded participants with 30 ≤ FLI < 60 (n = 41). Therefore, all participants that were eligible to enter the study were divided into two groups (FLI < 30, n = 17; and FLI ≥ 60; n = 122).

A total of 87.1 % of participants used oral antihyperglycemics [of them metformin, sulfonylureas, inhibitors of dipeptidyl peptidase 4 (DPP-4 inhibitors) were used by 81.8 %, 5.8 %, and 17.1 % patients, respectively], whereas 16.5 % of them were on insulin therapy. All participants who used lipid-modifying drugs (46.8 %) in our study used statins (100 % of them), whereas the smaller number of them used fibrates, also (4.6 %). Antihypertensive medication usage was recorded in 73.4 % participants [of them angiotensin converting enzyme inhibitors (ACE inhibitors), beta-blockers, and diuretics were used by 87.3 %, 20.6 % and 52.9 % patients, respectively].

All the participants provided written informed consent. The study protocol was approved by the Ethical Committee of Primary Health Care Center in Podgorica, Montenegro and the research was carried out in compliance with the Declaration of Helsinki.

 Anthropometric measurements

Basic anthropometric measurements: body height (cm), body weight (kg) and waist circumference (WC) (cm) were obtained, and body mass index (BMI) was calculated, as described previously [2, 19]. Waist-to-height ratio (WHtR) was calculated as waist (cm) divided by height (cm).

Biochemical analyses

Biochemical parameters were measured as previously described [19]. The blood samples were taken between 7–9 h a.m., after 12–14 h of an overnight fast. Samples were left to clot for 30 min and then centrifuged at 3000 rpm for 10 min.

Glucose levels were determined immediately after the blood was drawn, whereas serum samples used for other analyses were divided into aliquots and stored at ~ 80 °C before analyses. A whole blood in K2EDTA was used for determination of HbA1c, and it was measured with immunoturbidimetric assay (Roche Cobas 400, Mannheim, Germany).

Serum levels of glucose, total cholesterol (TC), high density lipoprotein cholesterol (HDL-c), low density lipoprotein cholesterol (LDL-c), triglycerides (TG), uric acid, bilirubin, aspartate aminotransferase (AST), alanine aminotransferase (ALT) and gamma-glutamyl transferase (GGT), were measured as described previously [19], using standardized enzymatic procedure (Roche Cobas 400, Mannheim, Germany). High sensitivity C-reactive protein (hsCRP) lev-
els were determined using a nephelometric assay (Behring Nephelometer Analyzer, Marburg, Germany).

Determination of serum AOPP was based on spectrophotometric detection of chloramine-T equivalents. In order to minimize the impact of storage time of samples as well as the possible influence of triglycerides and turbidity of samples, we modified AOPP assay by precipitating VLDL and LDL in the plasma. It was reported in a number of clinical disease states and method was developed in our previous reports [23].

Serum MDA levels were measured spectrophotometrically. The MDA determination by measuring TBARS by thiobarbituric acid (TBA) test is described as the most-commonly employed approach. It was reported as a true measure of MDA in a number of clinical disease states and in our previous reports [23].

Catalase (CAT) test is based on the release of oxygen from hydrogen peroxide (H₂O₂), by using the spectrophotometric assay based on formation of its stable complex with ammonium molybdate. Catalase activity determination was reported in a number of clinical disease states and method was developed in our previous reports [23].

Lipemic plasma was without influence on the CAT assay [23].

Blood pressure was measured and Glomerular filtration rate was estimated by using creatinine in the Modification of Diet in Renal Disease Study equation (eGFR MDRD) as described previously [19].

Statistical analysis
Data were presented as median (interquartile range) and compared by Mann–Whitney U-test. Comparison of categorical data given as absolute frequencies was performed with Chi-square test. Spearman’s correlation analysis was used to estimate the correlation between clinical parameters and FLI. Logistic regression analysis with enter selection principle was used to analyze determination of one or more independent or predictor variables (demographic characteristics, inflammation, lipid and oxidative stress markers) on the occurrence of fatty liver (dichotomous dependent variable). Also, it was used to identify independent determinants of FLI. Linear relationship between continuous predictor variables and the logit transformation of the dependent variable (FLI) was confirmed by Hosmer-Lemeshow test. Data are given as odds ratio (OR) and 95% confidence interval (CI) for odds. The explained variation in dependent variable was presented by Nagelkerke R squared (pseudo R²) value. The diagnostic potential of predictors was evaluated using Receiver Operating Characteristic (ROC) curve analysis. The area under ROC curve (AUC) was used as a measure how well predictors could distinguish between subjects that suffered from fatty liver from those who did not. All statistical calculations were performed using PASW® Statistic version 18 (Chicago, Illinois, USA) and the MedCalc® (Mariakerke, Belgium) Version 15.8. Two-tailed p values less than 0.05 were considered as statistically significant.

Results
The general characteristics of patients with DM2 divided according to the FLI values are indicated in ▶ Table 1. As expected, there were significant differences between groups in all parameters (except for height) which were used in FLI calculation. Body weight, BMI, WC, WHTR were statistically higher in the group with FLI ≥60 than in the group with FLI <30 (p<0.001 for all). Also, patients in the group with FLI ≥60 had significantly higher SBP than those in the group with FLI <30 (p<0.027). Duration of diabetes of patients in the group with FLI ≥60 was significantly shorter than in the group with FLI <30 (p<0.010). There were unequal distributions of patients with smoking habits, hypolipemic and antihyperglycemic therapies usages according to Chi-square test (▶ Table 1).

A significantly lower HDL-c concentration (p=0.003) was found in the group with FLI ≥60 than in the group with FLI <30 (▶ Table 2). In contrast, higher TG concentration (p<0.001) and high calculated indexes (e.g., TC/HDL-c ratio and non-HDL-c; p<0.001 and p=0.027, respectively) were evident in the group with FLI ≥60. These results were not unexpected, because TG concentration entered equation for FLI calculation. We also demonstrated significantly higher levels of glucose, hsCRP, uric acid, MDA and AOPP (p=0.038, p=0.002, p=0.033, p=0.001 and p=0.005, respectively) in the group with FLI ≥60 compared with the group with FLI <30 (▶ Table 2).

Spearman’s correlation analysis was used to test possible associations between FLI and examined clinical parameters in the cohort of patients with DM2 (▶ Table 3). We found a significant negative correlation between FLI and HDL-c (p<0.001), FLI and years of age (p=0.001) and FLI and diabetes duration (p=0.013). Positive correlations were evident between FLI and concentrations of glucose, HBA1c, hsCRP, MDA and AOPP (p=0.001, p=0.009, p<0.001, p=0.015 and p=0.019, respectively).

Multivariate logistic regression analysis was used to further investigate the associations of clinical parameters which were significantly different between the group with FLI ≥60, and the group with FLI <30, with fatty liver development, unadjusted and after adjustment for other risk factors (▶ Table 4). Unadjusted ORs showed that HDL-c, non-HDL-c, hsCRP, uric acid, MDA and AOPP had significant potential for fatty liver risk prediction. Also, unadjusted regression models correctly classified around 88% of patients in the group having fatty liver. Model 1 presented adjustment for fatty liver risk factors (e.g., age, gender, body height, smoking status, diabetes duration and drugs metabolized in liver) with HDL-c, non-HDL-c, hsCRP, MDA and AOPP respectively, and revealed that HDL-c, non-HDL-c, hsCRP and MDA were the independent risk predictors for fatty liver occurrence. As HDL-c concentration fall for 1 mmol/L, probability for higher fatty liver occurrence risk rose for 97.6% (OR = 0.024, p = 0.001). As non-HDL-c rose for 1 mmol/L, probability for fatty liver occurrence rose almost 3 times (OR = 2.725, p = 0.006). With increment in hsCRP concentration for 1 mg/L, probability for higher fatty liver occurrence risk rose for 37.9% (OR = 1.379, p = 0.043). Furthermore, with increment in MDA concentration for 1 μmol/L, probability for higher fatty liver occurrence risk rose for 12.0% (OR = 1.120, p = 0.001). (▶ Table 4).

In Model 2, the adjustment was performed for fatty liver risk factors (e.g., age, gender, body height, smoking status, diabetes duration, drugs metabolized in liver), together with HDL-c, non-HDL-c, hsCRP, MDA and AOPP. Results for Model 2 showed that HDL-c and MDA still kept significant prediction potential for fatty liver development (OR = 0.056, p = 0.029; and OR = 1.105, p = 0.016, respectively). Also, 50.8% of variation (given as Nagelkerke R² in ▶ Table 4) in fatty liver development could be explained by the Model 2. Furthermore, according to the Model 2, a total of 91.3% of patients could be correctly classified in the group having fatty liver.

Data are presented as median (interquartile range) and compared by Mann-Whitney test.
The aim of our study was to investigate the potential benefit of determining clinical parameters which were different between FLI groups in order to discriminate patients with DM2 with fatty liver disease from those who did not have it. ROC curves were used to achieve this (>Table 5). The calculated AUCs for the measurement of single clinical parameter (from 0.66 to 0.753) indicated that the clinical accuracy of the applied procedures was low. The same models were used in ROC analysis as in multivariate logistic analysis. The addition of fatty liver risk factors in Model 1 beside each clinical parameter (HDL-c, non-HDL-c, hsCRP, MDA and AOPP) increased the ability to discriminate patients with diabetes with and without fatty liver (AUC = 0.832, AUC = 0.808, AUC = 0.798, AUC = 0.824 and AUC = 0.743, respectively) (>Table 5, >Fig. 1). Model 2 improved discriminative abilities for fatty liver development. Calculated AUC was 0.909, which gave excellent accuracy of the applied procedure (>Table 5, >Fig. 2). Even more, the applied Model 2 had the highest sensitivity and specificity (89.3 % and 87.5 %, respectively) together than each predictor in Model 1, (>Table 5).

**Discussion**

In the current study we reported high prevalence of FLI-NAFLD, accounting for 87.8 % of participants with DM2 to have this metabolic disorder. Moreover, we observed an inverse association between age and FLI-NAFLD. The inverse association of FLI-NAFLD with age in our study differentiate this diabetic complication from established vascular complications, typically related to the duration of hyperglycemia [5].

Also, participants with FLI < 30 displayed longer duration of diabetes (>Table 1). Our results are in line with Giorda et al. [5] who showed in a large study comprising of more than 5,000 participants with diabetes, high prevalence of FLI-NAFLD (e.g., 61.3 %) which was more frequent among younger male patients or those with a shorter duration of diabetes. This unexpected results may be explained in part by diabetes treatment which may lower intrahepatic lipid content in the group with FLI < 30, which appear healthier despite longer DM2 duration.

To our knowledge, this is the first study examining the oxidative stress markers in relation to FLI-NAFLD in exclusively patients with DM2. We previously reported insulin resistance, higher inflammation (as measured with hsCRP), and increased adipokine level such as retinol-binding protein 4, as independent predictors of FLI-NAFLD in a cohort of postmenopausal, otherwise healthy women [2]. The current study extends those observations, suggesting that oxidative stress has independent influence on fatty liver development in patients with DM2.

Mitochondria and the endoplasmic reticulum of hepatocytes via the cytochrome P450 enzymes are the primary source of ROS, thus further leading to hepatic structural and functional disorders [24]. AOPPs indicates the overall status of the proteins in the cell/tissue, and in the states of increased oxidative stress they are created by reactions between plasma proteins and chlorinated oxidants [25].

Previous reports indicate that proteins are equally targeted by ROS as the lipids in diabetes [17], showing positive association between plasma levels of AOPPs and lipid peroxidation products. However, in the current study, after adjustment for confounding factors [4, 5, 26] we revealed that higher MDA, but not AOPP level was the independent risk predictor for fatty liver occurrence. This finding suggests that MDA is superior to AOPP in fatty liver risk prediction. Namely, even though that both MDA and AOPP significantly correlated with FLI-NAFLD in our study (>Table 3), and although higher AOPP levels were recorded in the group with FLI ≥ 60 (>Table 2), AOPPs were not retained in multivariate logistic regression analysis as independent predictor of fatty liver occurrence (OR = 1.014, p = 0.240; >Table 4). Nevertheless, in unadjusted model AOPP showed significant potential for fatty liver risk prediction.

Malondialdehyde (MDA) is reported to be a primary biomarker of lipid peroxidation of poly-unsaturated fatty acids that were attacked by ROS [25, 27] inducing multiple cellular alterations, influencing on the activity of mitochondrial respiratory chain, and generating more ROS, thus further increasing oxidative stress in NAFLD [18] and making a vicious circle between oxidative stress and NAFLD. Several previous studies also reported higher level of oxidative damage markers, such as MDA, in individuals with NAFLD [28–30].

On the other hand, no significant difference between groups in CAT activity was reported (>Table 2), although previous studies reported decreased CAT activity [28, 29] in the plasma of individuals with NAFLD.

Antioxidant enzyme CAT converts hydrogen peroxide into oxygen and water and thus neutralizes it, since hydrogen peroxide is a highly reactive molecule formed as a natural by-product of energy metabolism and may cause, like other ROS significant damages to proteins, lipids, and DNA [25].

No difference in CAT activity in low vs. high FLI-NAFLD risk group in our study may be explained by the assumption that liver tissue tries to counteract oxidative stress induced by elevated free fatty acids influx, by increasing expression and activity of antioxidant enzymes, even though they are shown to be progressively depleted as metabolic disorder occurs [17].

Model 1: adjustment for age, body height, diabetes duration (all continuous variables), gender, smoking habits, therapies (all categorical variables) and each predictor

Model 2: adjustment for age, body height, diabetes duration (all continuous variables), gender, smoking habits, therapies (all categorical variables) and all predictors

CI-Confidence interval; SE-Standard error
In the state of visceral obesity, increased free fatty acids hepatic influx enhance oxidative phosphorylation, leading to increase ROS/RNS production and oxidative stress, but also promoting inflammation through enhanced macrophage infiltration and increased secretion of broad spectrum of pro-inflammatory adipokines and cytokines, with consequent impairment of insulin action and dyslipidemia [12, 17, 18]. Inflammation in the adipose tissue may, therefore, precede hepatic inflammation [16]. In addition, secondary to insulin resistance, increased cellular uptake of free fatty acids without any subsequent β-oxidation contributes to the increased triglycerides production that, in turn, stimulates secretion of very low density lipoprotein (VLDL) in hepatocytes, further contributing to hepatic steatosis exacerbation [11, 12].

In our study, after adjustment for all fatty liver risk factors [4, 5, 26], HDL-c and MDA, still kept significant prediction potential for fatty liver (▶ Table 4).

Since the aim of our study was to investigate the potential benefit of determining markers of oxidative stress, inflammation and dyslipidemia in order to discriminate patients with DM2 with fatty liver disease from those who did not have it, we performed ROC analysis. It is important to note that Model 2 (which included confounding factors, and all five examined predictors, e.g., HDL-c, non-HDL-c, hsCRP, MDA, AOPP) improved discriminative ability for fatty liver development (AUC = 0.909). Even more, the applied procedure had the highest sensitivity and specificity (89.3 % and 87.5 %, respectively) together than each predictor in Model 1 (▶ Table 5), suggesting that multifactorial approach including oxidative stress markers, inflammation markers, and markers of dyslipidemia, could be of great benefit in discriminating patients with DM2 with FLI-NAFLD from those individuals with DM2, but without FLI-NAFLD. Also, high sensitivity of the applied procedure (nearly 90 %) could be used as a good screening procedure in order not to miss any patient having fatty liver disease and to detect this disorder as it really exists.

In addition, a very recent study proposed the extended FLI which significantly improves the power of the FLI to predict NAFLD [31]. Namely, the authors demonstrated that the fold-change of plasma triglycerides during a 2 h oral glucose tolerance test and 2 h glucose levels, together with the rs738409 C>G single nucleotide polymorphism in PNPLA3 may improve the power of the widely used FLI for NAFLD prediction.

The main disadvantages of the current study are the small sample size of our cohort and its cross-sectional design. Moreover, we have only calculated the FLI and had no direct measurements of hepatic steatosis, such as ultrasound, computed tomography, proton magnetic resonance spectroscopy or liver biopsy. Nevertheless, since FLI score ≥60 has been shown to have a good sensitivity and specificity for established NAFLD [21], we suggest that multifactorial and multimarker approach, including biomarkers of oxidative stress and inflammation, could be of benefit in identifying patients with DM2, having a great risk of fatty liver disease. Further studies are needed to confirm our results.

Conclusion
Prevention and/or early recognizing of non-alcoholic fatty liver disease is of urgent need in patients with type 2 diabetes mellitus. In addition to traditional risk factors for the onset and progression of fatty liver disease, multimarker approach including oxidative stress markers, markers of dyslipidemia, as well as inflammation markers could greatly improve the early identification of these patients with high risk of fatty liver disease and its consequences.
