Abstract

A 6-month-old infant was brought to the hospital with fever, vomiting, loose stools, and abdominal distension. The venous blood sample was sent to the hematology laboratory for complete blood count (CBC). Analysis of the sample on the automated hematology analyzer showed a discrepancy in red blood cell count, hemoglobin, and hematocrit values. Examination of the blood sample revealed a cherry red color appearance. On centrifugation, the plasma was lactescent. This finding provided an essential clue to the patient’s diagnosis of severe hypertriglyceridemia. Turbidity of lactescent plasma interferes with CBC. Analytical errors in the CBC using an automated hematology analyzer caused by lactescent plasma and methods to resolve the false values will be discussed in this case report.

Introduction

Hypertriglyceridemia may be due to primary or secondary causes. Primary hypertriglyceridemia is caused by either overproduction or defective clearance of various forms of lipids, which may be due to mutations in the genes involved in lipid metabolism. This can produce a lactescent plasma, the turbidity of which interferes with the complete blood count (CBC) estimation. In this article, we present a case of lactescent plasma found incidentally in a 6-month-old infant that, along with the other clinical findings, led to the diagnosis of familial hyperlipoproteinemia.

Case Presentation

A 6-month-old male infant was admitted for 2 days’ history of progressive abdominal distension, vomiting, and loose stools. He also had intermittent low-grade fever for 10 days. The infant was delivered at term through a normal vaginal delivery. The antenatal and postnatal periods were uneventful; he was exclusively breastfed since birth and had attained age-appropriate milestones. He was the second born of a nonconsanguineous marriage. There was no significant family history.

On examination, the child was alert and afebrile. General examination revealed no dysmorphic features and the vitals were stable. Abdomen examination revealed significant distension and massive hepatomegaly. Other systemic examinations were normal.

The blood sample sent for CBC analysis to the clinical pathology laboratory had a cherry red appearance, which, on centrifugation, separated into a creamy supernatant part (►Figs. 1 and 2). The blood sample was analyzed on an automated hematology analyzer (HA)—the Beckman Coulter...
LH-780. The HA generated CBC parameters as given in Table 1. This shows increased hemoglobin (Hb) and no correlation between the red blood cell (RBC) count, Hb, and hematocrit (Hct), that is, the rule of three that normally exists between these parameters was violated. The mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) were also found to be falsely elevated. The peripheral smear examination showed normocytic normochromic RBC with normal leukocytes and thrombocytosis. The hemoglobin repeated on a point-of-care instrument (EKF Diagnostics’ Hemo Control) gave a value of 13 g/dL.

Further investigations revealed markedly elevated triglyceride (TGL) of 13,450 mg/dL (normal <150 mg/dL) and very low-density lipoprotein (VLDL) levels of 1,784 mg/dL (normal <30 mg/dL), with hypercholesterolemia of 402 mg/dL (normal <170 mg/dL). The high-density lipoprotein (HDL) level of 12 mg/dL (normal 40–60 mg/dl) and low-density lipoprotein (LDL) level of 32 mg/dL (normal <110 mg/dL) were very low. Ultrasonography of the abdomen revealed hepatomegaly.

Ophthalmology evaluation revealed grade 3 lipemia retinalis in both eyes. There were no cutaneous xanthomas. The urine was screened for metabolic errors and showed negative results for mucopolysaccharides, 2,4-dinitrophenylhydrazine (DNPH) test for alpha-keto acids, ferric chloride test, and Benedict’s test for reducing substances. Liver function tests were within normal limits. With the clinical presentation of hepatomegaly together with laboratory evidence of lactic acidemia and elevated TGLs, a provisional diagnosis of familial hyperlipoproteinemia (type IV) was made.

The infant was started on a low-fat diet, statins, fibrates, medium chain TGL (MCT) oil, omega 3 fatty acids, and vitamin supplements. Lipid profiles were performed on the parents and the elder sibling, where were found to be normal. Because of the increased probability of acute pancreatitis, baseline serum amylase and lipase levels were done in the infant and were found to be normal. There was a significant reduction in serum TGL (372 mg/dl) and cholesterol (229 mg/dl) after 7 days.

The infant improved symptomatically and was discharged after a week of hospital stay. The parents were advised on weaning and low-fat diet in complementary feed. On review after 2 weeks, the infant was doing fine. A blood sample for deoxyribonucleic (DNA) analysis to rule out glycogen storage disease or hyperlipoproteinemia was sent to an outside molecular laboratory. The exome sequencing panel consisted of 6,120 genes for clinical interpretation. Clinically relevant mutations were annotated using published literature variants and disease databases. After analysis, no pathogenic variants causative of the above disorders were detected. Hence, the possibilities of transient infantile hyperlipidemia or secondary hyperlipidemia were considered in this case. Further investigations to rule out secondary hyperlipidemia were planned, but the child did not return for follow-up visits.

Discussion

Hypertriglyceridemia, defined as fasting serum or plasma TG > 150 mg/dL or above the 95th percentile for age and sex, can be caused by either primary or secondary disorders of TG metabolism. Primary hypertriglyceridemia is caused by a genetic defect causing overproduction and/or impaired lipoprotein removal. The impaired removal can be due to abnormal lipoprotein or its receptor. Familial hypertriglyceridemia is rare and has an incidence of 1 in 1,000 pediatric cases. Familial hyperlipoproteinemia (HLP) has been classified into five phenotypes by Frederickson. Secondary causes of hypertriglyceridemia in children include a high-fat diet, obesity, diabetes mellitus, renal diseases, hypothyroidism, some autoimmune disorders, β thalassemia major, and drugs (estrogen, antipsychotics, and tamoxifen). There are various methods to resolve spurious RBC values. Isovolumetric replacement of hyperlipidemic plasma after centrifugation with normal saline and ether extraction of lipids are some of the methods described. Alternatively, using a point-of-care instrument provides accurate hemoglobin results that are unaffected by hypertriglyceridemia. A study by Zeng et al found a simple step of low-speed centrifugation to give reliable results of RBC parameters in highly lipemic blood samples without any special equipment. After low-speed centrifugation of the blood sample, the separated plasma is removed and the remaining blood sample was rerun in the HA. A correction formula was used to calculate the correct Hb, MCH, and MCHC values. When a patient's sample is found to be lipemic, it is essential to notify the treating physician to determine the cause of hyperlipidemia. Early detection also provides appropriate management to the patient, preventing complications such as atherosclerosis, myocardial infarction, and acute pancreatitis in children.

Conclusion

Pathologists must be aware of preanalytical and analytical variables within the laboratory causing spurious CBC results. An appropriate protocol to identify lipemic samples and procedure to handle such samples should be established. Regardless of the interfering substance, there should be a prompt physician notification to ensure timely patient management.
