Abstract

Splenic abscess is a relatively uncommon condition, especially in pediatric malignancies. The diagnosis of a splenic abscess is a clinical challenge due to low incidence. The condition is fatal if not diagnosed on time. We are reporting two cases with underlying immune suppression secondary to malignancy and multidrug-resistant sepsis with splenic abscesses as the focus. Both children had life-threatening sepsis and required total splenectomy as a life-saving measure. Postsplenectomy course was uneventful with clinical improvement, and chemotherapy was continued. High suspicion is necessary due to nonspecific presentation. The treatment of splenic abscess includes conservative management and percutaneous drainage. Splenectomy is generally not indicated; however, total splenectomy may be required in the setting of multiple splenic abscesses, also to prevent overwhelming infection in an immunocompromised setting.

Introduction

Splenic abscess is an uncommon but life-threatening condition, especially in a pediatric oncology setting. Diagnosis is a challenge due to its nonspecific clinical picture.¹ The incidence of splenic abscess in children ranges from 0.05 to 0.7%.² Most cases of splenic abscess in children occur secondary to immunosuppression. The diagnosis can be made using imaging techniques such as computerized tomography (CT) and ultrasound (USG). Although broad-spectrum antibiotics for adequate duration and/or percutaneous drainage for treatment are sufficient in most cases, multifocal lesions necessitate splenectomy.³ We are reporting two cases of multidrug-resistant Klebsiella splenic abscess in children with cancer where splenectomy was performed as a life-saving measure.

Case Report

Case 1

A 12-year-old girl diagnosed with early combined medullary and central nervous system relapse of precursor-B cell acute lymphoblastic leukemia was undergoing salvage chemotherapy as per the UKALL-R3 protocol.⁴ She was planned for consolidation with an allogeneic hematopoietic stem cell transplant with a matched sibling donor.⁵

On day 13 of salvage induction chemotherapy, she developed a fever associated with signs of septic shock. She was managed with intravenous (IV) antibiotics (meropenem and amikacin) and also required inotropic support. Blood culture collected prior to the initiation of IV antibiotics showed growth of Klebsiella pneumonia which was

resistant to all antibiotics including reserved drugs like colistin and Fosfomycin. As per the antibiotic policy of the unit, her antibiotics were escalated to injection (Inj.) aztreonam and Inj. ceftazidime avibactam. Inotropic support and stress doses of steroids were given along with other supportive care measures like blood and blood products. Expecting prolonged postchemotherapy neutropenia and extensively drug-resistant klebsiella sepsis, granulocyte infusions were given on alternate days to combat infection. She subsequently became afebrile and subsequent blood cultures were sterile.

On day 29 of intensive phase chemotherapy, she developed abdominal pain associated with fever. Blood culture showed extensively drug-resistant (XDR) *Klebsiella* growth. Opinion from infectious disease department was taken, and she was restarted on Inj. aztreonam, Inj. ceftazidime avibactam and Inj. polymyxin were added. USG abdomen showed splenomegaly with multiple scattered hypoechoic tiny nodules. With a high suspicion of fungal infection in an immunocompromised child, antifungal (amphotericin B) was added. However, no improvement in symptoms was noted and blood culture again showed growth for *Klebsiella pneumoniae* with similar antibiotic sensitivity. CT abdomen confirmed splenomegaly with multiple intraparenchymal hypodensities of varying size (► **Fig. 1A**). With splenic foci as likely source for *Klebsiella*, emergency splenectomy was planned for the removal of source of infection.

Postsplenectomy, her fever spikes subsided and blood cultures came sterile. Pus culture sent from splenic tissue showed growth of *Klebsiella* with the same sensitivity. She was continued on chemotherapy and was planned for matched sibling donor allogeneic stem cell transplant with total body irradiation (TBI)-based conditioning.

Case 2

A 6-year-old girl with Stage IV Burkitt's lymphoma on inter-B NHL protocol (chemotherapy + rituximab)⁶ presented with

complaints of high-grade fever spikes and septic shock post-second maintenance phase of chemotherapy. She was started on infusion carbapenem and colistin as per unit protocol; however, blood culture revealed *Klebsiella* species resistant to all antibiotics including reserved drugs like colistin and fosfomycin. Her antibiotics were escalated to IV ceftazidime avibactam and aztreonam. Fever persisted despite giving reserved antibiotics and started developing abdominal pain in left flank. CT abdomen revealed splenic abscesses, and hence, an emergency splenectomy was performed for source control (► **Fig. 2A**).

Postsplenectomy, child had an uneventful course with clinical improvement and subsequent blood cultures became sterile. Pus swab from excised spleen showed the same growth and sensitivity pattern. She was continued on chemotherapy. Currently, she has finished treatment and is on follow-up for 9 months and doing well.

Approval from the ethical committee was taken. Written informed consent was obtained from the parents for the publication. The specimen of spleen on cut section in both cases revealed multiple soft greyish-white nodules suggestive of abscesses as shown in the image (► **Figs. 1B** and **2B**). Microscopy confirmed multiple abscess cavity with necro-inflammatory debris. Periodic acid-Schiff stain did not highlight any fungal elements.

Discussion

Splenic abscess is defined as an infectious suppurative process associated with macroscopic filling defect either in the parenchyma of the spleen or the subcapsular space.⁷ Splenic abscess is a rare life-threatening disease in children usually seen in immunocompromised patients due to the phagocytic immune functions of the spleen.⁸ Common predisposing factors in the literature include leukemia, malnutrition, sickle cell anemia, infection, and immunosuppression.⁹

Fig. 2 (A and B) Intraoperative finding of spleen near the lower pole and cut section of the spleen specimen showing multiple soft greyish-white nodules surrounded by congested splenic parenchyma largest measuring 1.8×1.5 cm suggestive of abscesses.

Splenic abscesses can be bacterial, fungal, or granulomatous.¹⁰ Most common organisms isolated from splenic abscesses include *Staphylococcus*, *Streptococcus*, *Salmonella*, and *E. coli*. As per the literature, gram-negative organisms are more common than gram positive.¹¹

Diagnosis can be delayed in children due to nonspecific symptoms, especially in immunocompromised conditions. In most cases of febrile neutropenia, detectable foci of infection cannot be identified and usually there are no localizing symptoms.¹² However, fever, left quadrant pain, and leucocytosis, which form the triad of splenic abscess,¹³ leucocytosis may be absent in immunocompromised patients.³ In our patients, fever and positive blood culture could have masked the diagnosis of splenic abscess. Persistent fever not responding to appropriate antibiotics and persistent culture positivity led us to look for deeper sites of infection. A high index of suspicion is needed for timely diagnosis. One should look and relook for other sources of infection in such conditions.

Broad-spectrum antibiotics for adequate duration is the treatment of choice in immunocompetent children.¹⁴ For larger abscesses, antibiotics alone may not be sufficient, and drainage may be required in addition.³ Percutaneous drainage is possible in unilocular or bilocular collections. Multilocular abscesses, ill-defined cavities, septations, and necrotic debris are unlikely to respond to percutaneous drainage.¹⁵

Bacterial and fungal infections are major clinical challenges in patients with prolonged severe neutropenia secondary to intensive chemotherapy. Functional white blood cells are essential to combat infection. In a leukemic child, there is neutropenia and/or neutrophil dysfunction. The role of granulocyte transfusions in neutropenic patients with infection is very well known. In case 1, due to persistent neutropenia and extensive drug-resistant organisms in blood culture, granulocytes were transfused on an alternate day basis from day 3

after first positive culture until neutrophil count recovery. A median dose of granulocyte was 2.1×10^{10} /bag (range: $1.12 - 3.4 \times 10^{10}$). A total of three units of granulocytes were transfused. No granulocyte infusion was done in case 2.

Fungal splenic abscess is a very well-known complication during therapy in hematolymphoid malignancies.^{16,17} However, case reports on bacterial splenic abscess are very few.^{3,7,12} Chiang et al reported 29 cases of splenic abscess, 5 of which were pediatric patients. Fungal splenic abscess was noted in 28% cases, compared to bacterial abscesses which were 19%. The success rate of 75% with antibiotics alone was documented in the study; however, the abscess was solitary in 21 cases (72%).⁷ In our cases, as the abscess was multilocular and failed to respond to IV antibiotics, splenectomy was required.

Splenectomy plays a critical therapeutic role as a definitive treatment for abscesses of the spleen.¹⁸ The procedure is generally avoided due to the important immunological functions of the spleen.¹⁹ Partial splenectomy can be done if the abscess is in the lower pole. In the immunocompromised child when multiple abscess is present, total splenectomy is required to prevent overwhelming infection and recurrence. The role of splenectomy in splenic abscess in immunocompromised children has been discussed in the literature. Ferraioli et al discussed a series of 16 cases of splenic abscess where two patients with leukemia required splenectomy as response to IV antibiotics was poor.²⁰ Another case report by Olcay et al showed successful management of splenic abscess with splenectomy in a 14-year-old boy with acute myeloid leukemia.¹² Management of splenic abscess in immunocompromised children was discussed by Smith et al who opined that splenectomy should be the choice for the treatment of splenic abscess in immunocompromised children and in patients with multiple splenic abscesses due to difficulty in eradicating the infection from the reticuloendothelial cells of the spleen, which are not well penetrated by systemic antibiotics.²¹ Ng et al also

suggested splenectomy for multiple abscesses as the safe and effective treatment choice.²² Dissemination to other organs including the brain and kidneys is a known risk and sometimes progresses to chronic discharging sinuses into a hollow organ with high mortality rate.³ In our patients, repeated culture growing drug resistant gram-negative sepsis not responding to any antibiotics, worsening clinical condition and plan for future TBI as a pre-HSCT conditioning in case 1, splenectomy was considered before deciding to go for total splenectomy for removal of infective source and as a life-saving measure. In both cases, the postsplenectomy significant improvement in the clinical condition with the clearance of XDR infection was noted and chemotherapy could be continued. With timely intervention, the risk of rupture and dissemination leading to mortality was prevented. Delay in chemotherapy administration is known to cause high risk of relapse. In our cases, we were able to prevent further delay in chemotherapy due to infection, and remission was achieved.

Overwhelming postsplenectomy infection secondary to splenectomy is a well-known complication in splenectomized patients. Both our patients were on intensive chemotherapy, and splenectomy was performed on an emergent indication; hence, presplenectomy vaccination was not done. Postsplenectomy, penicillin prophylaxis was continued in both cases, and in case 2, after 1 year of completion of chemotherapy (+ Rituximab), vaccination including capsulated organisms was given and since then the child has been doing well.

Primary splenic abscess is a rare manifestation in children with cancer. A high index of suspicion coupled with timely diagnosis will lead to choosing the best modality of therapy. Wait and watch policy in an immunocompetent individual may not be suitable.

Declaration by Authors

The manuscript has been read and approved by all the authors, the requirements for authorship have been met, and the manuscript represents honest work.

V.B.K. and V.M.V. conceived of the presented idea. R.R.B. and S.J. collected the case details and did the literature search. A.M.V., V.K., S.P., and V.G. contributed to the manuscript design and figures. All authors discussed the results and contributed to the final manuscript.

Declaration of the Patient Consent

The authors certify that they have obtained all appropriate patient consent forms.

Funding

None.

Conflict of Interest

None declared.

Acknowledgment

None
