Transnasal percutaneous endoscopic gastrostomy (PEG) is not possible in some patients due to difficulty in opening the mouth (e.g., in patients with head and neck cancers, oral submucous fibrosis, dental misalignment, and intermaxillary fixation). Transnasal endoscopy has been used for diagnostic upper gastrointestinal endoscopy and for placement of enteral feeding tubes [1,2]. However, the small diameter of the accessory channel in transnasal instruments (2 mm) limits their use for therapeutic interventions [3]. A study of transnasal percutaneous endoscopic gastrostomy (TN-PEG) using pediatric scopes (with an outer diameter of 7.9 mm) reported failure of the method in three of six patients [4]. TN-PEG using standard-diameter endoscopes has been reported [5].

We prospectively studied the feasibility of TN-PEG using a standard-diameter endoscope in six patients (five men, one woman; median age 50). Transoral PEG was not possible in these patients due to dental misalignment in four cases, and due to postoperative anatomy in patients who had undergone head and neck surgery in two cases. The nostrils were inspected to identify the more patent nostril and to determine whether a deviated nasal septum was present. The wider nostril was sprayed with 10% lidocaine, followed by the application of lubricant jelly. After intravenous sedation with midazolam 2 mg, an Olympus GIF-Q140 instrument (outer diameter 9.8 mm) was introduced through the nostril and was negotiated through the nasal cavity under vision. Pushing was used to advance the scope if the lumen was slightly narrow. Once the nasopharynx had been successfully negotiated, the subsequent steps were carried out in the same way as in transoral percutaneous endoscopic gastrostomy. A 20-Fr Bard tube with markings was placed using the pull technique. The tapered and stiff dilating portion of this tube is 7 cm long and requires gentle and cautious pulling.

The procedure was successful in five of the patients; the one failure was due to the presence of a narrow nasal cavity. Complications included mild epistaxis in two patients. We then studied five patients (four men and one woman) using GIF 160 (OD 8.6 mm) and TN-PEG was successful in all.

TN-PEG is therefore feasible in selected patients. Important factors for success are patency of the nasopharynx (Figure 1), the diameter of the endoscope, and the characteristics of the PEG tube used (Figure 2).
