

## Endoscopic Diagnosis and Treatment of an Esophageal Bezoar Resulting from Bulk Laxative Ingestion

The finding of a bezoar during gastrointestinal endoscopy is not frequent, and the location is generally in the stomach (1,2), although it has been described as an occasional finding in the esophagus (3–5). The material of the bezoar can vary, but it is generally composed of hair or dietary nonabsorbable fiber. We present here the case of a 66-year-old man with a history of chronic constipation, who had been treated with a bulk laxative consisting of plantago ovata seeds in granular form. The patient was referred to our service with acute dysphagia and retrosternal pain. The patient's previous medical history was essentially unremarkable, except for an episode of esophagitis diagnosed as hiatal hernia with minimal gastroesophageal reflux that had been treated with ranitidine for the previous two years. The physical examination was normal.

During endoscopy, a localized mass in the distal third of the esophagus was visualized, completely occluding the lumen (Figure 1). This corresponded to a bezoar that was fragmented into multiple pieces and partially extracted with the help of a polypectomy snare (Figure 2), allowing the endoscope to be advanced into the stomach along with some fragments of the bezoar.

To our knowledge, only five cases of esophageal bezoars have been previously described (3–5). Although the incidence of this complication is rare, the increasing use of bulk laxatives may favor the development of this disorder.
