Ascending pneumonia complicating endoscopic therapy of a pancreatic abscess

A 71-year-old man with multiorgan failure caused by necrotizing pancreatitis was discharged from the intensive care unit after a 6-week stay. Two weeks later he developed a spiking fever, abdominal tenderness, and an abdominal mass. Computed tomography revealed a large pancreatic abscess that was compressing the duodenum and gastric wall (Fig. 1). Because of the interposition of bowel, transectaneous drainage was risky and an endoscopic approach was chosen. After transmural duodenocystic puncture and dilation, a 7-Fr double-pigtail stent and a nasocystic tube were inserted. The patient developed dyspnea and a spiking fever, abdominal tenderness, and an abdominal mass. Chest radiography revealed patchy infiltrates in the lower lobe of the right lung. Enterococcus faecium, Klebsiella oxytoca, and Candida glabrata were grown from cultures of the aspirate from a pseudocyst. The patient died 2 days after the cystogastrostomy because of complicated septic multiorgan failure after a long period of intensive-care treatment.

Whereas early mortality in severe acute pancreatitis is due to the systemic inflammatory response syndrome, late mortality of pancreatitis is determined by the development of secondary infection of necrotic tissue or pseudocysts [1]. Infection of pseudocysts leads to pancreatic abscess, a common complication of severe acute pancreatitis with a mortality of around 9% [2]. Several case series have proposed an endoscopic approach for the treatment of both infected pancreatic necrosis and perigastric pancreatic abscesses. Success rates of 90% for complete resolution of infected necrosis or abscess have been reported [3,4], although hemorrhage and perforation have been described as complications of these interventions [5].

The causal relationship linking a nosocomial pneumonia with an endoscopic procedure performed several days before can be difficult to confirm. In this case, however, the microbiological results for the cystic aspirate and the bronchoalveolar lavage effluent were identical, and the close temporal relationship between the endoscopic intervention and the pneumonia suggests that the pneumonia must be regarded as a complication of that intervention.
