A 75-year-old man presented with hematemesis and melena. He had received an uncovered nitinol self-expanding metal stent (SEMS) 2 months previously for inoperable obstructive hilar cholangiocarcinoma.

Upper endoscopy revealed a normal esophagus, stomach, and duodenal bulb. At the duodenal wall opposite the papilla, a large ulceration with hematin spot (Fig. 1) had formed as a result of SEMS impaction. We decided to shorten the stent with argon plasma coagulation (APC). This procedure we used a duodenoscope and an ERBE generator (APC settings: power 80 W, flow rate 1.8 l/min-ute). The section was done circumferentially 1 cm from the papilla (Fig. 2), and the stent was shortened by 1.5 cm (Fig. 3). During his hospitalization the patient was making progress and his hematocrit was stable. He was discharged 4 days later.

He presented again to our hospital the next day with massive hematemesis and melena. At admission he was already in severe oligemic shock and succumbed shortly afterwards.

Ulceration is caused by continuous mechanical irritation of the mucosa opposite the distal end of the stent. Distal migration or malpositioning are the causes of this complication. Furthermore, mucosal ulceration may be promoted by the sharp edges of metal stents [1]. In most cases, bleeding was self-limiting. When indicated, endoscopic hemostasis successfully arrested the bleeding.

APC is reported to be a safe, effective, and easy way to reduce stent length [2]. Shortening of the stent, with or without endoscopic hemostasis, was enough to permanently correct the complication in the published cases.

Fatal upper gastrointestinal bleeding caused by a metal biliary stent despite stent shortening with APC
