Abstract
Congenital duplication of facial nerve is a very rare anomaly commonly associated with inner and middle ear anomalies. There can be duplication of mastoid, tympanic, or labyrinthine segments. We describe duplication of mastoid segment of facial nerve in a young female who also showed middle ear anomalies and external auditory canal atresia.

Key words: Chorda tympani nerve; computed tomography; facial nerve; stylomastoid foramen

Introduction
Duplication of facial nerve is a very rare anomaly commonly associated with middle and inner ear anomalies. It can involve any segment of intratemporal facial nerve. It is important to look for this anomaly in all patients with congenital deafness and ear anomalies. Knowledge of this anomaly is useful in presurgical evaluation to avoid inadvertent nerve injury and also in recognizing associated middle and inner ear anomalies.

Case Report
A 15-year-old female presented to the ENT department at our hospital with history of progressive hearing loss detected at school age. There was no history of either pus discharge or ear pain. Also, there was no history of any congenital infection, trauma, or any surgery. Clinical examination showed well-formed pinna with atresia of external auditory canal. There was conductive type of hearing loss. No facial nerve abnormalities were detected. Audiometry study showed low-frequency hearing loss in the right ear up to 60 dB. Patient underwent high-resolution computed tomography (HRCT) of temporal bone in our department.

HRCT temporal bone showed atresia of the right external auditory canal. Middle ear ossicles were dysplastic with hypoplastic malleus which was fused with deformed incus [Figure 1]. Stapes was absent. The inner structures, cochlea, vestibule, and semicircular canals, were unremarkable. We traced the course of facial nerve and found duplication of mastoid segment of facial nerve with two stylomastoid foramina on the right side [Figure 2]. Mastoid segment of the facial nerve divides into lateral and medial segments with larger lateral segment branch which carries enlarged chorda tympani branch and medial segment branch continues as tympanic branch of the facial nerve [Figure 3]. There was no duplication of tympanic and labyrinthine segments of the facial nerve [Figure 4].

Discussion
Facial nerve anomalies are commonly associated with ossicular chain anomalies. This is explained by the fact that ossicular structures develop from the first and second branchial arches and facial nerve develops from the second arch. Congenital dehiscence of tympanic segment of facial nerve is the most commonly seen anomaly of the facial
Duplication of facial nerve is a very rare anomaly associated with middle and inner ear anomalies. Bifurcation of mastoid, tympanic, labyrinthine, and canalicular segments of facial nerve has been variously described in the literature. Bifurcation of tympanic segment is most frequently reported and can be associated with congenital stapes fixation and oval window atresia. Labyrinthine segment division is an extremely rare occurrence with a single case report in the literature. There are few isolated case reports describing bifurcation of mastoid segment of the facial nerve. In patients with external auditory canal atresia, often the facial nerve shows altered course with mastoid segment passing along or through the atretic bone plate resulting in increased risk of injury during surgical repair. Other variations in facial nerve course in this anomaly include anterolateral displacement of stylomastoid foramen with extracranial course of facial nerve making it vulnerable for injury during surgery.

HRCT of temporal bone accurately depicts the facial nerve anatomy and its anomalies. Bifurcation of mastoid segment is shown on CT as division of facial nerve at the level of stylomastoid foramen with symmetric bifid facial nerve segments coursing in two stylomastoid foramina. The lateral foramen contains the enlarged chorda tympani branch and courses in close relation to mastoid bone. It is important to recognize this anomaly as there is risk of nerve injury during mastoidectomy or cochlear implant placement. Bifurcation of tympanic segment of the facial nerve usually occurs adjacent to oval window, with reunion of bifid segments distal to stapes or at posterior genu. Bifid segment of the facial nerve courses over oval window with increased risk of injury during stapedectomy, and hence it is important to recognize this anomaly. Division of labyrinthine segment of the facial nerve is extremely rare and is associated with cochlear and vestibular anomalies. Bifurcation of intracanalicular part of the facial nerve with separate or no bony septa has been described.

Conclusion

Facial nerve duplication is a rare anomaly often associated with middle and inner ear anomalies. It is important for the radiologist to be aware of this entity and carefully look for this anomaly while reviewing CT of temporal bone. Major presurgical implication of this anomaly can avoid...
inadvertent injury to the facial nerve during surgery. Also, recognizing this anomaly should alert the radiologist to look for other anomalies.
