Abstract

Serous psammomacarcinoma of ovary is a rare ovarian carcinoma. We present the imaging features of this condition in a patient with a probable metastatic subcutaneous nodule.

Key words: Computed tomography; ovary; psammoma bodies

Introduction

Serous psammomacarcinoma of ovary is a rare and infrequently described variant of ovarian cancer, characterized histologically by the presence of psammoma bodies.[1] We present the imaging features in one such case that was associated with subcutaneous nodules.[1] Till date, as per our knowledge, only 28 case reports have been published.[2] These carcinomas respond well to chemotherapy, and recurrence of disease after surgical resection is reported to below.[3]

Case Report

A 54-year-old female presented with a history of vague abdominal discomfort and loss of appetite for the last 8 months. She had also noticed increase in abdominal girth and loss of weight. Her routine blood investigations were normal. A computed tomography (CT) scan showed heavily calcified abdominopelvic mass lesions, which were more in the pelvis, and multiple calcified nodules scattered throughout the abdomen (over the liver surface, ligamentum teres, lesser sac, and in both paracolic gutters) [Figure 1]. There was an incidental Morgagni hernia with calcified nodules within [Figure 2]. There was moderate ascites. Calcified subcutaneous nodules were noted in both gluteal regions [Figure 3]. A diagnosis of serous psammomacarcinoma of ovary was made on the basis of the imaging findings. The CA 125 level was elevated, with a value of 33,231 U/ml (normal 0–35 U/ml). Biopsy taken from the pelvic mass showed all the classic features of serous psammomacarcinoma of ovary. There were gross psammoma bodies in the biopsy specimen, with moderate desmoplasia and stromal invasion of the tumor. Tumor cells also showed minimal pleomorphism, with mildly increased mitosis and signet cells [Figure 4].

Discussion

Serous psammomacarcinoma of ovary is a rare tumor presenting between 36 and 76 years of age.[3,4] It commonly arises from the ovary but is also known to arise from the peritoneum.[5] It may mimic a calcified fibroma if the lesion is restricted to the pelvis.[2] Histologically these tumors show classical psammoma bodies. Pathophysiologically, psammoma bodies are formed by deposition of mineral crystal on single, necrotic, degenerated tumor cells with progressive deposition on the outer layers, causing a
lamellated appearance. As these psammoma bodies are deposited in necrotic tumor cells, they may actually represent a growth halting process of the tumor and may act as a barrier for spread. In serous psammomacarcinoma of ovary, these psammoma bodies are associated with more than 75% epithelial cell clusters, with moderate cytological atypia and tissue or vessel invasion. Biochemically, CA 125 is an important marker for ovarian carcinoma and is commonly elevated.

Clinically, these patients usually present with abdominal discomfort and increasing abdominal distension.

Radiologically, this tumor has classic and pathognomonic features. There are calcified lesions in one or both ovaries and, if there are peritoneal or distant metastases, then those lesions also show calcification. Some important conditions to be considered in the differential diagnoses of such multiple calcified lesions in abdomen are pseudomyxoma peritonei, undifferentiated abdominal malignancy, tuberculous peritonitis, meconium peritonitis, and mucinous adenocarcinoma of stomach. Our patient also showed a mass arising from both ovaries as well as metastases to the peritoneum and liver surface, the ligamentum teres, the lesser sac, and both paracolic regions. In addition, our patient had a Morgagni hernia with a calcified deposit within it along with calcified deposits in the subcutaneous region, which have been only rarely described.
presume that the subcutaneous lesion was a metastatic
deposit, as similar subcutaneous metastatic deposits have
been described earlier.\[1\] Psammomacarcinoma has a better
prognosis as compared to other carcinomas of the ovary.\[7\]
However, some reports have suggested a more aggressive
behavior as well.\[5,6\] Risk of recurrent disease following
surgical resection is reported to be low.\[1\]

**Conclusion**

Psammocarcinoma of ovary is a rare ovarian tumor with
classic radiological findings of multiple calcified lesions
in the abdomen and pelvis. The condition should be
considered in the differential diagnosis when multiple
calciﬁed lesions are seen in the abdomen.
