Abstract
Although [18F] 2-fluoro-2-deoxy-D-glucose (FDG) is the most widely used radiopharmaceutical the world over, it is not the ideal tracer for brain imaging, owing to its high physiological cortical uptake and lack of specificity. This has paved the way for the introduction of several novel radiotracers, each with their own inherent strengths and limitations. We present the insights gained from the use of these radiotracers at our institution.

Key words: Brain tumor; Novel Positron emission tomography radiotracers

Introduction
Positron emission tomography/computerized tomography (PET/CT) has gained widespread acceptance in tumor evaluation owing to its ability to detect tumors and define their extent, provide information that aids planning of radiotherapy and operative interventions, show response to treatment, and detect tumor recurrence. [18F] 2-fluoro-2-deoxy-D-glucose (FDG) has been aptly called the molecule of the millennium because of the impact it has had in the field of oncological imaging. In fact, the first oncological application of PET was in the assessment of brain tumors.[1] FDG PET/CT has been utilized primarily in brain tumors for grading and characterization, prognostication, guiding the selection of the site for biopsy, and evaluation of therapeutic response with modest accuracy. However, it has its limitations, primarily the lack of specificity[2] and the high physiological cortical uptake. This has led to the development and utilization of newer non-FDG radiopharmaceuticals. We present the insights gained with the use of these non-FDG radiopharmaceuticals in brain tumor evaluation at our institution.

Discussion
At present FDG is the most widely used radiopharmaceutical the world over. This is due its favorable half-life of 110 minutes (which does not necessitate an on-site cyclotron), high uptake in tumor tissue, and relatively low positron range. The basis for high FDG uptake in tumor tissue is the high metabolic rate and therefore increased glucose utilization in tumor cells. However, FDG may not be an ideal imaging agent for brain tumors as there is a high physiological glucose uptake in normal brain parenchyma, glucose being an obligatory energy substrate for brain. This leads to intense radiotracer uptake in normal brain tissue, and, as a result, low grade tumors, small tumors, and tumors with early recurrence may go undetected. Moreover, FDG uptake is relatively nonspecific and is seen to occur in inflammatory and granulomatous tissues also.

A variety of non-FDG PET radiotracers with oncological applications have been developed. These include radiotracers for amino acid synthesis, Deoxyribonucleic acid (DNA) synthesis, lipid synthesis, hypoxia, angiogenesis, and peptide receptors.

Radiotracers for amino acid synthesis

11C methionine
Protein synthesis is a fundamental prerequisite for tumor
growth. There is an upregulation of protein metabolism and cell-mediated transport of amino acids in tumors. Radiotracers that can measure the increase in protein synthesis will have increased sensitivity and specificity as compared to FDG. Several such radiopharmaceuticals have been developed. Of these, \textsuperscript{11}C-labelled methionine has been the most widely studied. Unlike with FDG, the normal brain parenchyma exhibits overall reduced uptake of \textsuperscript{11}C methionine. The pituitary gland shows increased uptake [Figure 1]. It has thus proven superior to FDG in the evaluation of brain tumors as its reduced uptake in healthy brain tissue results in enhanced contrast between the brain tumor and the surrounding normal parenchyma.\textsuperscript{[9]}

Despite its obvious advantages, \textsuperscript{11}C methionine has certain limitations. The short half-life of twenty minutes necessitates an on-site cyclotron. Further, it takes some time for the radiotracer \textsuperscript{11}C to bind to various physiological substrates, further reducing the amount of radioisotope available in the final radiopharmaceutical by the time it is ready for injection. However, it has been found to be more efficacious than FDG PET/CT both for the primary detection of tumor and for delineation of its extent [Figure 2]. Additionally, it can differentiate tumorous from nontumorous lesions with a high degree of sensitivity and specificity.\textsuperscript{[4]}

A semiquantitative estimate of the level of radiopharmaceutical uptake in a particular tissue can be made by calculating the standardized uptake value (SUV). The ratio of radiotracer uptake in the pathological region to that in the contralateral uninvolved cortex can then be calculated. A threshold of 1.48 of relative \textsuperscript{11}C methionine uptake between tumor and normal tissue has been found to yield a high sensitivity of 83% and a specificity of 92%.\textsuperscript{[5]}

This is of particular relevance in the Indian setting, where the incidence of intracranial tuberculomas and other inflammatory granulomas is high. These lesions often mimic tumors clinically as well as on imaging studies. \textsuperscript{11}C methionine has demonstrated good results in distinguishing tuberculomas from neoplasia [Figures 3 and 4].

Owing to its selective uptake in brain tumors, \textsuperscript{11}C methionine PET/CT has also been found to be a useful modality for assessing the size and margins of gliomas that may not enhance on contrast-enhanced Magnetic resonance imaging (MRI) imaging.\textsuperscript{[6]}

It also plays an important role as a marker for cell proliferation and angiogenesis\textsuperscript{[5]} and can be used to evaluate tumor grade in gliomas, thus allowing better tumor prognosis.\textsuperscript{[8]}

It plays an important role when planning the radiotherapy field and for guiding selection of the site of radiotherapy.
D’Souza, et al.: Novel positron emission tomography radiotracers in brain tumor imaging

Figure 3 (A-D): Posterior fossa glioma. Contrast-enhanced axial (A) and sagittal (C) MRI images show a conglomerate ring-enhancing lesion (arrow) that was mistaken for a tuberculoma. Axial fused FDG PET/CT image (B) shows low-grade FDG uptake (arrow). Axial fused 11C methionine PET/CT image (D) shows uptake (arrow), consistent with a high-grade malignancy. Note normal uptake in the pituitary gland.

Figure 4 (A-D): Posterior fossa tuberculoma. Axial (A) and coronal (C) contrast enhanced MRI images show conglomerate ring-enhancing lesions (arrow) in the left cerebellar hemisphere. Axial non-contrast CT scan (B) and fused 11C methionine PET/CT (D) images show rounded lesions (arrow) with surrounding edema with reduced tracer uptake. Increased radiotracer uptake in the pituitary fossa region is noted again.

biopsy. 11C methionine is useful for discriminating between tumor recurrence and radiation necrosis [Figures 5 and 6], a situation where CT scan, MRI, and FDG PET are often inconclusive. However, there have been a few instances of 11C methionine uptake in nonmalignant conditions as well, such as brain abscesses and conditions wherein the blood-brain barrier is disrupted as in intracranial hematomas. The increased radiotracer accumulation noted in some of these cases may be a reflection of overall increased cell metabolism, although the exact mechanism is unclear [Figure 7].

Other amino acid tracers
Malignant transformation increases the use of aminoacids for energy, protein synthesis and cell division. Owing to the short half life of 20 minutes that 11C methionine has, its use has been limited to institutions with an on-site cyclotron. Aminoacids labeled with a radiotracer having a longer half-life would be preferred in the routine clinical setting. Of these, 3,4-dihydroxy-6-18F-fluoro-L-phenylalanine (FDOPA) and O-(2-[18F]fluoroethyl)-L-tyrosine (FET) have been widely studied. Their uptake is mainly related to carrier mediated active transport, which is upregulated in tumor cells. These amino acids are retained in tumor cells, which exhibit higher metabolic activities than most normal cells. The superiority of FDOPAPET over FDG PET for imaging low-grade tumors and evaluating recurrent brain tumors has been demonstrated in past studies [Figures 8 and 9]. Low-grade tumors are frequently FDG negative. However, as both high- and low-grade tumors show increased avidity for this radiotracer, it may not be useful for assessing tumor grade. One important advantage however is that tracer uptake is independent of blood–brain barrier breakdown, thus facilitating radiotracer uptake independent of tumor enhancement on contrast MRI studies.

FET PET when combined with MRI significantly improves the identification of cellular glioma tissue. In addition, high- and low-grade brain tumors can be differentiated on the basis of the different uptake kinetics of FET. It has also proven useful in differentiating malignant from benign lesions of the brain.

Radiotracers for Deoxyribonucleic acid synthesis
DNA synthesis is an important prerequisite for cellular proliferation. The most widely used radiotracer for assessing DNA synthesis is 3-deoxy-3-[18F] flurothymidine.
D’Souza, et al.: Novel positron emission tomography radiotracers in brain tumor imaging

(FLT). This compound gets phosphorylated by thymidine kinase, which shows markedly increased activity in proliferating tumors, and thereafter gets trapped within the cell. The imaging of cellular proliferation has a potential advantage over glucose imaging because FLT is specific to tumors, while high levels of energy metabolism are also seen with other processes including inflammation. Thus, unlike FDG it does not show uptake into inflammatory cells and has been widely used to distinguish benign from malignant pulmonary lesions. Although this differentiation may not always be feasible, the possibility of using FLT for monitoring treatment with cytostatic anticancer drugs needs to be explored. Like \(^{11}\)C methionine, the background uptake in normal brain parenchyma is low, thus enhancing tumor detection [Figure 10].

Radiotracers for lipid synthesis

\(^{11}\)C- and \(^{18}\)F-labeled choline have been used in brain tumors. The basis for this is the increased transport and phosphorylation of choline in tumor cells, where it gets incorporated into the phospholipids of the cell membrane.

Figure 5 (A-D): Brain stem glioma, post-radiotherapy. Axial T1W MRI images (A,B) show the glioma as a hypointense lesion (white arrow in A) that does not enhance on contrast administration with another hypointense lesion (black arrow in B) in the left middle cerebellar peduncle, which shows intense enhancement (black arrow) on a contrast-enhanced T1W axial MRI image (C). Axial fused \(^{11}\)C methionine PET/CT image (D) shows tracer uptake in the former, suggestive of an active lesion, with absent uptake in the latter due to post-radiotherapy changes.

Figure 6 (A-D): Contrast-enhanced CT scan(A,B) show a left frontal grade II fibrillary astrocytoma (post-surgery and post-radiotherapy) with a peripherally enhancing cavity (arrow) that is equivocal for tumor residue/post-radiotherapy changes, which was also the case on a contrast-enhanced MRI (not shown). Axial FDG PET/CT image (C) shows no radiotracer uptake (arrow). Axial \(^{11}\)C methionine PET/CT (D) shows increased uptake anteriorly (arrow), and this was later proven to be tumor residue on biopsy.

Figure 7 (A-C): Neurocutaneous melanosis. Sagittal contrast-enhanced MRI image shows intensely enhancing areas of leptomeningeal thickening along the cerebellar folia, cerebral sulci, and ependyma (arrows). Sagittal FDG (B) and \(^{11}\)C methionine (C) PET/CT images show intense uptake (arrows) at the corresponding sites. However, there was no evidence of malignant transformation on biopsy.
It has been found useful for the differentiation of low-grade from high-grade gliomas, but not for distinguishing low-grade gliomas from nonmalignant lesions. In a comparative study of FDG, $^{11}$C methionine, and $^{11}$C choline in 95 gliomas, $^{11}$C methionine was found to be the most superior among the three.

**Radiotracers for hypoxia**

Adequate tumor vascularization is an important precondition to tumor growth. Inadequate vascularization would culminate in tumor hypoxia and eventual necrosis. Hypoxic tissue is inherently more resistant to chemotherapy or radiotherapy and this is often responsible for failure.
of chemo-radiotherapy and an overall poor response. Several in vivo PET tracers have been developed to assess tumor hypoxia, e.g.,[18]F fluoromisonidazole (FMISO) and 64/60Cu(II)-diacetylbis (N-4-methylthiоsemicarbazоne) (64/60Cu-ATSM), which have a propensity to accumulate in hypoxic rather than normoxic cells.[18] The most extensively used radiotracer for hypoxia is FMISO (Figures 11 and 12).[19] Inclusion of FMISO imaging data provides information that is complementary to FDG PET data by correlating metabolic activity to tumor hypoxia. In a comparative study on glioblastomas, the biological aggressiveness assessed by serial MRI was seen to be linked with the hypoxic tumor burden assessed on FMISO-PET.[20] This aids the selection of alternative treatments and monitoring of their therapeutic efficacy.

Other radiotracers

The next generation of PET tracers includes those that will bind to specific cancer-related receptors or antigens.[21] These agents would offer tremendous opportunities for selective imaging, thus increasing the sensitivity and specificity for a particular tumor. There would also be enormous potential for directing molecular therapies targeted at these neoplasms. The development of targeted radiolabeled drugs to explore the efficacy of anticancer regimens holds promise for the future.

Conclusion

A multitude of PET radiotracers has emerged for the assessment of brain tumors, each with its inherent strengths and weakness. There is a pressing need to undertake comparative trials of the various tracers so that we can select the best tracer for any given clinical situation.

Author Help: Online submission of the manuscripts

Articles can be submitted online from http://www.journalonweb.com. For online submission, the articles should be prepared in two files (first page file and article file). Images should be submitted separately.

1) First Page File:
Prepare the title page, covering letter, acknowledgement etc. using a word processor program. All information related to your identity should be included here. Use text/rtf/doc/pdf files. Do not zip the files.

2) Article File:
The main text of the article, beginning with the Abstract to References (including tables) should be in this file. Do not include any information (such as acknowledgement, your names in page headers etc.) in this file. Use text/rtf/doc/pdf files. Do not zip the files. Limit the file size to 1024 kb. Do not incorporate images in the file. If file size is large, graphs can be submitted separately as images, without their being incorporated in the article file. This will reduce the size of the file.

3) Images:
Submit good quality color images. Each image should be less than 4096 kb (4 MB) in size. The size of the image can be reduced by decreasing the actual height and width of the images (keep up to about 6 inches and up to about 1800 x 1200 pixels). JPEG is the most suitable file format. The image quality should be good enough to judge the scientific value of the image. For the purpose of printing, always retain a good quality, high resolution image. This high resolution image should be sent to the editorial office at the time of sending a revised article.

4) Legends:
Legends for the figures/images should be included at the end of the article file.
