Abstract

Background: Bone marrow edema is assumed to be caused as a result of trabecular microfractures that are detected by MRI. As MRI is not widely available in countries like India, this study aims to encourage the use of DECT in detection of bone edema as evidence with comparable efficiency to MRI. Aim: To assess the diagnostic accuracy of dual-energy CT in detecting bone marrow edema in patients of trauma of lower limb and correlate it with MRI. Setting and Design: It is a cross-sectional study. Materials and Methods: The study included 40 patients of age 15–70 years irrespective of sex. All the patients of lower extremity trauma underwent DECT and MRI evaluation after clinical evaluation. All the images were postprocessed on a work station and were further evaluated by a radiologist. Results: Mean attenuation at fractured site observed by Dual energy CT was found to be significantly higher as compared to that at adjacent site (170.75 ± 33.99 vs. 19.73 ± 22.50 HU). The sensitivity and specificity of dual energy CT as compared to MRI in detecting bone marrow edema were 94.1% and 91.3%, respectively. Of the 40 cases enrolled in the study, agreement of MRI and Dual energy CT was observed in 37 (92.5%). Conclusion: Dual energy CT can be an effective alternative to MRI in the detection of bone marrow edema in patients of lower limb trauma. Dual energy CT can also be used in patients in whom MRI is contraindicated.

Key words: Bone marrow edema; DECT; lower limb; trauma
MeSH Terms: Bone marrow edema, lower limb trauma, MRI

Introduction

The terms “bone bruise,” “bone contusion,” or “bone marrow edema” are used synonymously but have important clinical issue among patients with traumatic injuries with recognition of its role as a significant pain generator.[1,2] Bone marrow edema is assumed to be caused as a result of trabecular microfractures. It is responsible for pain even in the absence of substantial soft-tissue injuries.[3] Bone marrow edema remains undetected in radiographs. On MRI, marrow edema is seen as an area of signal loss.

on T1-weighted images involving the bone with increased signal intensity on T2 weighted and STIR images.[4] Despite MRI being the most widely known technique for assessment of bone marrow edema, in conditions where MRI is contraindicated, bone marrow edema remained undetected and undiagnosed for years interfering with overall healing and rehabilitation of patient. Fortunately, DECT has emerged as a viable alternative in such situations as DECT makes attenuation measurements at tube voltages of 80 and 140 kV that can be subjected to three material decomposition, allowing for mathematical subtraction of substances with a relevant photograph-electric effect, such as iodine or calcium. The same technique is used to calculate a virtual noncalcium image from an unenhanced image, which would make bone marrow accessible for CT diagnosis.[5]

Despite the promising role of DECT in the assessment of bone marrow edema, in general and traumatic bone edema in particular, there have been limited clinical studies evaluating its usefulness. Considering this gap, we planned our study to assess the diagnostic accuracy of DECT in detecting bone marrow edema in patients of trauma of lower limb and correlate it with MRI.

Materials and Methods

A cross-sectional study was conducted on 40 patients over a period of 18 months. Patients, irrespective of sex aged 18–70 years with lower extremity trauma and suspected fracture were included in the study. Pregnant females, patients with metallic implants were excluded from this study.

For all patients with lower extremity trauma, CT examinations were conducted using a dual-energy CT system (384 slice Somatom Force; Siemens Healthcare, Erlangen, Germany) equipped with two X-ray tubes (tubes A and B with two different voltages, 80 and 140 kv). Acquisitions of the injured knee joint and ankle joint images were performed with a dual-energy protocol. The dual-energy CT examination parameters used were as follows: tube A: tube voltage of 80 kV, reference current time product of 250 mAs; tube B: Sn140 kV, where Sn indicates the use of an integrated tin filter; reference current time product of 150 mAs, 1280.6 mm collimation, 0.6 pitch, 0.5 seconds rotation time. Intravenous contrast material was not used in each patient.

All the images were postprocessed on a workstation using Syngo Via software that allowed analysis of images using three material decomposition. It acquires the attenuation measurements from two different kV settings and calculates a virtual noncalcium (VNCa) image, using the three-material decomposition method. To further improve the assessment of the marrow space, a special filter technique, the Selective Photon Shield, is also applied. VNCa images were present in the form of color-coded images (bone marrow setting in Syngo Dual Energy). Axial, sagittal, and coronal multiplanar color-coded reformations were all created for further assessment and analysis.

The information was color-coded with a color lookup table which codes bone marrow and edema in shades of green-yellow to orange-red (parallelly to the progressive increase of density); 3D volume rendering maps coding bone marrow edema in shades of green and normal bone in blue were used.

After initial CT, MRI of the affected part was performed. The examinations were performed with an MRI system (Hitachi, Aperto), 0.4 T using the dedicated coil for knee and ankle. The site was evaluated with T1-weighted (at TR = 600 ms, TE = 11 ms), PD/T2-weighted (at TR = 3000 ms, TE = 33 ms) images (FoV = 160 mm, matrix = 320 mm × 320 mm, thickness = 3 mm) and STIR images. All images were analyzed on a workstation using a software that allowed for three-dimensional reconstructions and measurements. Bone edema was identified as per the protocol described by Pache et al.[6] Upon DECT Image analysis, dual-energy color-coded region were evaluated whether edema existed in the bone marrow or not. If edema existed in the bone marrow, it displayed in green or yellow on the dual energy color-coded images; then the circular regions of interest (ROIs) over each region on the dual-energy color-coded images and in the adjacent region. The ROIs were placed at the location of highest edema intensity, which was green or yellow on the color-coded images, to obtain attenuation values. MRI findings were considered as final. On analysis of the MRI images, the diagnosis of BME was based on signal intensity increase in the STIR and T2 images with a signal decay at T1-weighted imaging. All the observations were made by three observers. Final observation was made when there was agreement of two or more observers.

Results

In our study, 40 patients with lower limb trauma and suspected fracture were analyzed. In majority of the cases, we encountered trauma and fracture around knee joints and the time gap between injury and DECT ranged from 6 to 24 days.

In the present study, three patients (7.5%) had ankle injury while remaining 37 (92.5%) had knee injury as shown in Table 1. Incidentally, knee injuries were predominant.

In this study, mean attenuation at fractured site was observed as 170.75 ± 33.99 HU while the same at adjacent site was observed as 19.73 ± 22.50 HU as shown in Table 2.
The difference in attenuation at fractured site and adjacent site among the patients enrolled in the study was found to be 151.03 ± 35.03, which was considered statistically significant. Subjective interpretation by DECT based on attenuation found bone marrow edema in 45.0% cases [Figures 1, 2A, 2B, 3A and 3B] while in rest of the cases no edema was found [55.0%; Table 3].

On MRI evaluation, bone marrow edema was found to be present in 42.5% cases only [Figures 2C And 3C] while in rest of the cases (57.5%) edema was not found [Table 4].

Both DECT and MRI indicated presence of edema in 16/17 cases whereas DECT indicated edema in 2 cases that were not indicated by MRI [Table 5].

Sensitivity, specificity, PPV, and NPV of DECT against MRI for detection of bone marrow edema was found to be 94.1%, 91.3%, 88.9%, and 95.5%, respectively. Diagnostic accuracy of DECT against MRI was found to be 92.5%. Among the 17 cases in which MRI indicated the presence of edema, the attenuation of DECT was higher (152.47 ± 33.16 HU); as compared to 23 cases where MRI indicated no edema [149.96 ± 37.03 HU; Table 6].

Difference in attenuation among cases where MRI indicated edema or no edema was not found to be statistically significant.

**Discussion**

Traumatic bone injuries are not just limited to bone fractures and soft tissue injuries, but they have an impact on bone marrow too. The bone marrow edema pattern represents a “footprint” of the injury mechanism and improves diagnostic confidence in the detection of concomitant injuries.\[6\]

In recent years, Dual Energy Computed Tomography has emerged as a promising alternative for assessment of posttraumatic bone marrow edema with encouraging accuracy.\[5,7-17\] In this study, we used the dual-energy CT virtual noncalcium technique to assess bone marrow with MR imaging serving as a standard of reference. Because of the ability of DECT to subtract calcium from cancellous bone, it was able to depict bone marrow edema.

In present study, a significant difference in mean HU units was observed between fracture site and adjacent site, thus reflecting a possibility of bone marrow edema. Similar to findings of present study, Ai et al. reported a significant difference of ~55.8 HU was seen in CT numbers (HU) with higher CT numbers at fracture site compared to adjacent normal tissue. In their study, they also compared the fracture site with contralateral side and found a significant difference between two sites. In the present study, though we did not include the contralateral side and found that the differences between fracture site and adjacent normal tissues reflected the possibility of bone marrow edema. Wang et al., in line with our study, found a significant difference in the mean CT number of the affected site and adjacent normal tissue. Similar observations were reported by Pache et al. in their pioneering study too.

In the present study, out of 40 patients, 18 (45%) were found to have bone marrow edema by DECT whereas bone marrow edema was detected in 17 (42.5%) cases by MRI. The findings suggested that DECT had a higher positivity rate as compared to MRI. Similar to the findings of present study, Guggenberger et al. also reported a higher positivity rate for DECT (23.3% and 24.3% for observer 1 and observer 2) as compared to MRI (17.8%). However, Seo et al. in their study reported a lower positivity rate for DECT (15.9% and 20.6% for observer 1 and observer 2) as compared to MRI (22.3%). Ali et al. while evaluating traumatic acute wrist fracture bone marrow edema reported the positivity rate for DECT to be 16.1% as compared to 15.6% for MRI. In the present study, we had included both knee and ankle fractures.

As far as diagnostic efficacy of DECT against MRI was concerned, the present study found DECT to be 94.1% sensitive and 91.3% specific. They reported a positive predictive and negative predictive value of DECT as 88.9% and 95.5%, respectively. There was a substantial agreement between DECT and MRI (κ = 0.848). In their pioneering assessment, Pache et al. also reported >80% and >90% sensitivity and specificity of DECT in the detection of bone marrow edema. Guggenberger et al. in their study reported that the sensitivity and specificity of DECT were 90% and 80.5% by one observer and 90% and 81.6%, respectively, as compared to MRI. However, Seo et al. in their study reported that the sensitivity, specificity, positive predictive value, and negative predictive value of DECT for bone bruises were 65.4%, 98.2%, 91.4%, and 90.8%, respectively, for Reader 1 and 70.3%, 93.6%, 76.0%, and 91.7%, respectively, for Reader 2. In the present study, though we included three observers and took the observation made by two or more observers as the final observation, we achieved a more objective assessment which proved out to be more sensitive and specific. Karaca et al. upon using MRI as the reference standard, DECT had a sensitivity, specificity, positive-predictive value, and negative-predictive value and accuracy of 89.3, 98.7, 95.4, 96.9 and 96.6%, respectively, for assessment of bone marrow edema in vertebral fractures. The findings of the present study emulated them. Ai et al. reported even a higher sensitivity and specificity of DECT (100% sensitive and 99.5% specific) upon evaluating bone marrow edema in wrist fractures.

**Conclusion**

The present study showed that DECT is a useful method for evaluation of traumatic lower extremity fractures for the presence of bone marrow edema. The findings of the present study endorsed the findings of previous studies that have also shown that DECT can be used as an alternative to MRI for evaluation of traumatic injuries suspected from bone marrow edema. Addition of DECT as an alternative will help in providing an additional tool, where MRI facility is contraindicated and could reduce the long-term burden of
bone marrow edema. Further studies to validate the findings of the present study are recommended.
