INTRODUCTION

Polydactyly of the foot is among the most common congenital anomalies of the foot. It is characterized by six toes, with or without duplication of the corresponding metatarsals or phalanges [1]. The manifestations of polydactyly of the foot may range from vestigial soft-tissue masses to an additional fully formed digit. Depending on the position of the extra toe, polydactyly of the foot can be classified as preaxial, central, or postaxial. Among these, the postaxial type is the most frequently encountered [2]. Watanabe et al. [3] proposed a dichotomization of these abnormalities based on their appearance on radiography.
as fifth or sixth ray duplications (with phalangeal or metatarsal bifurcation, respectively). When the condition involves syndactyly of the fourth and fifth toes, it is referred to as polysyndactyly, which is characterized by a dominant fifth toe and a hypoplastic sixth toe.

Simple excision of the extra toes does not yield satisfactory results due to the diverse and complicated shapes of polysyndactyly of the foot. The choice of which toe to excise has a significant effect on the postoperative outcome and cosmesis, and remains a controversial issue. The commonly described treatment for postaxial type polysyndactyly involves resection of the fifth toe to preserve the neurovascular bundles of the fourth and sixth toes [4,5]. However, the sixth toe is occasionally noticeably short of reaching the arcade of toes, with disfigurement of the toenail. The sixth toe also has a variable degree of lateral axis deviation, which requires wedge osteotomy of the proximal phalanx to achieve better alignment with the remaining toes. The traumatic process of wedge osteotomy can lead to shortening of the phalanx with circulatory compromise, and this procedure does not consistently yield satisfactory outcomes.

The literature contains insufficient information regarding the management of polysyndactyly of the foot. This study aimed to introduce an individualized method for treating patients with postaxial polysyndactyly of the foot by sparing the fifth toe and removing the short and deviated sixth toe. We also compared the surgical results to those of the previous method, which involved saving the sixth toe instead of the fifth, to verify the advantages of this individualized method.

METHODS

Patients and data collection

We retrospectively evaluated 38 patients with postaxial polysyndactyly of the foot with short and deviated sixth toes who underwent surgery by a single surgeon (STK) between September 2006 and July 2019. We compared 18 cases treated by sparing the fifth toe to 20 cases treated by sparing the sixth toe. Cases of polysyndactyly without syndactyly, bilateral cases, and syndromic cases were excluded from the study. The patients’ demographic characteristics and clinical information were extracted from their medical records. The SAM system was used to classify the anomalies using preoperative X-rays and medical photographs [6]. This study received approval from the Institutional Review Board (IRB No. 2003-088-1109). All patients provided written informed consent prior to enrollment.

Assessment

Objective results were determined via anterior-posterior (A-P) foot X-rays. The forefoot width was determined preoperatively by measuring the distance between the widest points of soft-tissue margins in the transverse axis of the foot (Fig. 1, A). This point was typically at the level of the interphalangeal joint of the great toe and proximal interphalangeal (PIP) joint of the sixth toe. The orderly alignment of the toes’ arcade was then evaluated by comparing the angle difference in the alignment of toes before and after surgery (Fig. 1, B). Two lines connecting the midpoints of the tips of the two outermost adjacent toes were drawn on A-P foot X-rays. The angle between the two lines was measured. Lastly, the fifth and sixth toe length before surgery and the fifth toe length after surgery were measured as the distance between the tip of the distal phalanx to the base of the proximal phalanx (Fig. 1, C). A postoperative evaluation was performed at the final follow-up session. In each patient, the affected side was compared to the unaffected side before and after surgery.

As the participants were too young to cooperate, their guardians subjectively evaluated the outcomes based on appearance and current symptoms using a similar method to that used by Phelps and Grogan [7]. Outcomes were evaluated in the following areas: symptoms, callosities, residual deformities such as valgus or varus deformities, and cosmetic appearance. A “satisfac-
“tory” rating was given to patients with no pain, callosities, or residual deformities who had a cosmetically acceptable appearance. If a suboptimal evaluation was given in any of the four categories, the patient’s outcome was rated as “unsatisfactory.”

Surgical technique
In the fifth toe-spared group, the fourth and fifth toes were separated via an interdigital zigzag incision, taking care not to disrupt the medial neurovascular bundle of the fifth toe (Fig. 2A). After confirmation that the neurovascular bundles of the fifth toe were intact, a second interdigital zigzag incision was made at the lateral side of the fifth toe to expose the phalangeal bones and metatarsal bone. The sixth toe was excised while preserving the medial portion of the head of the proximal phalangeal bone to prevent instability and stiffness of the PIP joint.

In the sixth toe-spared group, an interdigital incision was made between the fourth and fifth toes (Fig. 2B). After exposure of the phalangeal bones, the fifth toe was removed. If the sixth toe was laterally deviated, wedge osteotomy was performed at the proximal phalanx and fixated with two or three Kirschner wires. In both groups, the remaining skin defect between the fourth and fifth or sixth toe was covered using full-thickness skin harvested from the inguinal area to achieve tension-free wound closure. After application of an aseptic compressive dressing, a short leg splint was applied for 10 days.

Statistical analysis
Results are presented as the mean ± standard deviation. The unpaired t-test, Pearson chi-square test, and Wilcoxon rank-sum test were used for between-group comparisons. The statistical analyses were conducted using PASW Statistics 18 (SPSS Inc., Chicago, IL, USA). P-values < 0.05 were considered to indicate statistical significance.

RESULTS
The demographic information and clinical features of the patients are shown in Table 1. No significant differences were found between the two groups regarding sex distribution, the

average age at the time of surgery, and follow-up duration. There were no S0-type cases in either group, given that all patients had some degree of syndactylyism with the adjacent toe. All cases were M0 with no metatarsal involvement of the extra digit.

Table 2 shows the forefoot width, angle difference, and toe length before and after surgery in both groups. The postoperative ratio of the affected to unaffected side was calculated for each category. The closer the ratio was to 1, the greater the similarity between the affected and unaffected sides. No significant difference was found between the two groups regarding the forefoot width ratio. However, the angle difference ratio significantly differed between fifth toe-spared group and sixth toe-spared group (1.23 vs. 1.59, P < 0.05). The toe length ratio also significantly differed between the two groups (0.99 vs. 0.74, P < 0.01).

Satisfaction with the results showed a significant difference between the two groups (P < 0.05) (Table 3). In the fifth toe-spared group, guardians were satisfied with the overall appearance of the foot and the spared toe, without residual deformity or lateral deviation (Figs. 3, 4).

There were no postoperative complications such as wound dehiscence, wound infection, bone growth delay, or bone malunion in either group until the final follow-up visit. However, in the fifth toe-spared group, there were two cases of hypertrophic scarring, which were not sufficiently severe to necessitate additional surgery, and one case of callus formation, which required reoperation. In the sixth toe-spared group, there was one case of hypertrophic scarring, one case that resulted in total loss of the

toenail (Fig. 5), and three cases of valgus deformity, of which one required reoperation of wedge osteotomy 2 years after initial surgery.

DISCUSSION

Polydactyly of the foot is among the most commonly encountered anomalies of the limbs, and accounts for 45% of congenital foot abnormalities [8-10]. This condition results from established genetic syndromes in some cases, but most frequently occurs as an isolated trait with an autosomal dominant pattern of inheritance and variable expressivity (gene penetrance) [11]. Polydactyly of the feet primarily affects the fifth toes, while polydactyly of the hand most commonly affects the third and fourth fingers of the hands, with partial or complete digital duplication within the affected web [12,13]. This condition involves a dominant mutation with variable expression in the HOXD13 gene, which encodes a transcription factor that plays an essential role in the development of the limbs [14]. Altered HOXD13 expression affects the embryonic development of the foot, resulting in polydactyly [12].

Numerous suggestions have been made regarding the classification of polydactyly of the foot. Conventional classifications are based on only morphology and do not reflect surgical planning or predict postoperative outcomes. In this study, the SAM system [6] was used for classification. This system can be used to customize surgical methods and preoperatively predict outcomes such as residual deformities. The category of syndactyly (S) reflects the requirement for skin grafts during surgery. In this study, all patients received skin grafts. The category of axis deviation (A) measures the axis deviation of the toe to be preserved and indicates the need for wedge osteotomy. The average axis deviation of the toe to be preserved was 21.3° in the fifth toe-spared group and 30.5° in the sixth toe-spared group. In the fifth toe-spared group, no cases required wedge osteotomy, whereas 85% of cases needed wedge osteotomy in the sixth toe-spared group. The category of metatarsal extension (M) describes the extent of metatarsal duplication. All of our cases were classified as M0, indicating no involvement of the metatarsal bone. Therefore, the primary purpose of reconstruction in this study was to achieve aesthetic improvement, rather than functional improvement.

Decisions regarding which toe to excise and the method by which this is achieved are regularly encountered clinical issues.
An advantage of sparing the fifth toe is that excising the lateral sixth toe is an easier approach than excising the medial fifth toe. Furthermore, it is markedly less complicated than on-top plasty, but still yields highly satisfactory results. Although dividing the fourth web space and excising the sixth toe puts the fifth toe at risk of damaging the neurovascular bundles on both sides, there was no circulatory compromise, wound problems, or toe loss in this study. The preserved fifth toe exhibited no axis deviation and did not require wedge osteotomy, and the toe length was comparable to that of the unaffected side. Therefore, we recommend sparing the fifth toe if the sixth toe is too short or laterally deviated (A1 and A2 in the SAM classification).

In previous reviews, it was pointed out that excision of the lateral toe can lead to two common complications: valgus deformity and postoperative pain due to callus formation [7,18,19]. In this study, one case in the fifth toe-spared group experienced painful postoperative callus formation, which required removal 2 years after the primary surgery. However, there were no cases of valgus deformities. During the procedure of preserving the fifth toe, a small component of the proximal phalanx of the sixth toe was preserved to support the middle phalanx of the fifth toe. The disadvantage of this procedure is a relatively thick fifth toe after surgery due to the presence of two bones in the proximal phalanx. However, the thickness was not unpleasant enough to reduce cosmetic satisfaction or induce any discomfort while wearing shoes.

In this study, the angle difference was used as a measurement to reflect both the length and lateral deviation of the most lateral toe. This parameter indicated the degree of order in the arcade of the toes. If the most lateral toe is either very short or laterally deviated, the angle difference is larger, reflecting a disturbance of the orderly arcade of the toes. In sixth toe-spared group, the angle difference on the affected side did not always improve postoperatively. The preserved sixth toe was short and became shorter after wedge osteotomy, which led to a greater angle difference.

The limitations of this study include the relatively short follow-up period for confirming the postoperative results. The A-P foot X-rays used for measurements were not consistently acquired vertically above the foot with full extension of all toes due to difficulties in the cooperation of the children. Additionally, the children’s guardians assessed subjective satisfaction, instead of the children themselves. However, the results were compared between two similar demographic groups of patients. In each group, values were compared in ratios to overcome the varying rate of growth in children. This study also provided exact numbers for critical lengths and angles, which reflect aesthetic aspects of the foot. Nonetheless, further research is needed to assess the vascular structure of the fifth toe accurately. Subsequently, assessments of the tendon, ligament, and movement of the toe should be conducted using magnetic resonance imaging and ultrasonography to reinforce the final decision.

In cases of postaxial polysyndactyl in which simultaneous web reconstruction is required, the medial toe tends to be excised. However, in cases with short sixth toes with axis deviation, sparing the fifth toe reduces the need for wedge osteotomy, yielding a safe and effective treatment with high cosmetic satisfaction.
